“AI exposure mainly threatens entry-level tasks, so experienced workers are safe.” The employment pattern inverts part of that assumption while the expertise problem runs deeper. In the most AI-exposed US occupations, workers aged **22–25 saw a 16% relative employment decline (Oct 2022–Sep 2025)** while those **35–49 grew over 8%** — protection that attached to accumulated expertise. But the pipeline that produces that expertise runs through the entry-level work now being reduced, so the protection is time-limited in a way the cross-sectional figure hides. **Expertise regeneration is itself at risk**: if the formative work disappears, the cohort that would become the experienced practitioners is smaller.

“Lifelong learning means adults taking more courses.” Course-taking is one delivery form of a broader requirement: maintaining and rebuilding competence as the tasks change. A workforce that needs continuous regeneration is not short of course offerings; it is short of the practice opportunities where new competence is actually formed.

“Lifelong learning is a personal responsibility, so institutional design is secondary.” The regeneration problem is structural — it concerns where formative work exists at all — and individuals cannot create the work their own development requires. Framing it as motivation explains nothing about the 16% decline concentrated at the bottom of the age distribution.

Implications for Practice

For employers and training designers

- Protect the formative work that builds expertise, not only the tasks that deliver output. If entry-level work is removed, the senior practitioners of ten years hence were not hired.
- Build structured practice with feedback into continuous development, since competence regeneration depends on doing the harder version of the work under supervision, not on course completion.
- Track progression by cohort, not only by headcount. A workforce can grow overall while its entry pipeline narrows.

For educators and course designers

- Design for working adults' constraints: short, spaced, and applicative, so that practice survives contact with employment.
- Make the pathway from assisted to independent performance explicit, since the offloading risk is highest for learners whose practice is entirely tool-mediated.

For researchers and policymakers

- Report employment effects by age band rather than as an aggregate displacement figure; the 16% versus 8% contrast is the finding.
- Study where formative work is disappearing, since that is the mechanism by which current gains become future shortages.

Workplace Learning

> **Workplace learning** — the use of AI for workforce development, corporate learning, and professional skill acquisition. Professional training extends AI in education beyond formal schooling into workplace and lifelong learning contexts.

Questions to Consider

- Think of a skill you learned on the job rather than in a classroom. What made that workplace learning effective, and how might an AI coach replicate or improve it?
- The page's Workforce Readiness Level framework suggests the highest competency stages are 'gated by industry-embedded experience rather than coursework.' What does that imply for how we should train people—and for the limits of AI Simulation?
- Virtual patients and training simulators let professionals practice safely. What kinds of judgment and interpersonal skills might a simulator struggle to capture, no matter how realistic?
- The 'Dual Train Problem' is the tension between rapidly changing AI skills and the slower pace of policy and curriculum. If you could choose durable competencies to prioritize for learners today, what would they be?
- Adult learners balance work and study, often through screens. How might AI-powered professional training both enable and complicate that balancing act—especially around data, trust, and time?

Introduction

AI in professional training

- **Simulation and practice:** Virtual patient training and ATCO training simulators create AI-powered professional practice environments. In teacher education, AI role-play simulation extends this into practice-based teaching: Student GPT simulated a misconception-holding middle-school math student so preservice teachers could practice diagnosing and remediating student errors, aligning with the "approximations of practice" of practice-based teacher learning as an affordable complement to costly platforms like TeachLivE.

Wang et al. (2026) add a coaching-policy lesson: fading assistance against the learner's estimated competence cut simulator lap time 27.9% ($p = 0.005$) and failures by 3.52 per lap, whereas rule-based fading on a fixed schedule produced no reliable lap-time change. - **A voluntary, text-only rehearsal moved nothing.** Of 201 first-year medical students offered a GPT-4o patient before their first standardized-patient class, 49 used it, and nervousness, preparedness, Self-Efficacy and self-perceived competence did not differ from the 84 controls; 6 of 19 non-users who gave a reason cited technical or login problems (Jongkind et al. (2026)). - **Lifelong learning integration:** Lifelong Learning and Adult Learners research connect professional training to continuous education. - **Agents built to deliberate rather than answer.** Cowhitt and Gibson (2026) design instructional agents for teacher professional learning that withhold the answer and

press the teacher to justify a decision, drawn from 33 deliberation codes across 8 clusters. - **Public sector:** Public sector AI adoption examines training in government contexts. - **Workforce readiness frameworks:** Smith et al. propose a Workforce Readiness Level (WRL) framework that adapts the Technology Readiness Level scale into nine competency stages scored across four pillars (digital/AI literacy, cyber-physical fluency, human-machine collaboration, data-driven decision making), under a "no-thin-pillar" rule. Evidence from smart-manufacturing capstones shows the highest readiness stages are gated by industry-embedded experience rather than coursework — pointing to work-integrated learning as essential to professional AI training. - **Instructor and employer priorities diverge.** A survey of 500 US instructors and an employer panel agreed on the importance of only one of 26 AI skills — setting realistic expectations for AI-augmented work — and only three of the 26 were taught by half or more instructors (Fried (2026)). - **Domain-specific PD evidence is thin.** A systematic review of language educators (Li et al. 2026) found only three of 23 studies reported structured professional development, yet those that did converged on gains in knowledge, confidence, and identity — evidence that structured, domain-specific training (pairing technical skill with practical wisdom) is both scarce and effective, and that PD should move from awareness-raising and ethics through hands-on tool mastery to co-design of AI-enhanced lessons. - **Teacher educator professional development as model-building:** Eyal (2025) ran a year-long 180-hour course in which 22 higher-education teacher educators co-designed the Adaptive Artificial-Intelligence-Literacy Model, replacing fixed competency ladders with three inter-related axes (context fit, professional needs, dynamic development) and a 20-item reflective Self-Assessment questionnaire. The design premise is that AI literacy is situational: a pre-service teacher in a resource-limited setting, a subject teacher, and a principal need different competencies, so professional development should target role-specific judgment rather than a standardized rubric. - **A technical profession's AI practice can outrun its teaching pathway.** In a 560-record review (Scopus 426, PubMed 1, IEEE 133), Morales-Cevallos et al. (2026) found 21 empirical studies, 18 technical and only 3 educational. Their curriculum argument rests on the apprentice model's limits, algorithmic literacy as a foundational requirement, and explainability under cross-examination; yet their six-pillar framework was not prespecified or validated, and the only student sample, a K-12 program in Korea, tested no training intervention with forensic professionals. - **What training should target:** the field's measurement base lags the technology it describes. In a systematic review of 33 teacher AI literacy instruments, Zainal, Mohd Matore and Maat (2026) found that 29 (87.9%) targeted general AI concepts while only four (12.1%), all published in 2025, addressed generative AI. If instruments track what training is meant to build, that distribution marks generative-AI competence in teaching as the least measured and most urgent target for professional development. - **Workforce forecasting:** Fletcher et al. review U.S. gray literature on AI and the engineering/computing workforce, framing the "Dual Train Problem" (rapid change vs. urgent policy) and recommending that higher education prioritize durable AI competencies, Ethics and AI Governance, and skill-based credentials aligned with emerging roles (e.g., Prompt Engineering, AI auditing, AI policy) to sustain human-centered work in an automated economy. - **Skill-sustaining designs lose under throughput metrics.** de Jong (2026) argues that reflective interaction contradicts the faster-decisions, higher-throughput promise driving AI adoption in professional work: a controlled study can absorb the friction, an environment measuring performance by speed or quantity cannot, and where rivals offer equivalent support without friction, skill-sustaining designs become a competitive disadvantage — a problem the paper says may belong to organizational policy or government rather than interaction design. - **Oral assessment for workplace capability.** A TVET design study addresses a long-standing mismatch between text-heavy assessment and the verbal, situational capabilities that professional qualifications certify, using an Large Language Models

(LLMs) to support interactive oral assessment. Across four cohorts the voice format was rated realistic by 21 of 33 learners with no dissenting response on its advantage over a written portfolio, and the system ran fully offline on one laptop for up to 12 simultaneous learners, deleting recordings after 90 days and leaving scoring to assessors (Designing AI-Supported Oral Assessment in TVET). It is a concrete example of AI widening the range of assessable competence in professional-training rather than only automating existing written formats. Its cohorts, though, were Level 3 automotive and engineering classes, so the evidence sits in initial vocational provision rather than in the workplace upskilling this page covers. - **The meeting is where understanding becomes assessable.** When a generative tool drafts the analysis, a polished research update no longer shows whether a trainee understands the work, so Prunuske and Adams-Phillips (2026) propose three diagnostic windows for research meetings (metacognitive calibration, conceptual explanation, collaborative sensemaking) with prompts that surface what a summary left out.

- **Institutional conditions, not national context, explain readiness gaps.** A comparative survey of 568 university faculty in Chinese (n = 340) and Kazakhstani (n = 228) faculty development centers (Bi, Araily, Lyu & Xiu, 2026) found Kazakhstani faculty ahead on all seven GenAI readiness dimensions at baseline, with the largest gaps in disciplinary transfer, prompt design, and AI-supported assessment. Hierarchical regression dismantled the national explanation: the country difference fell sharply once prior GenAI use and recent training entered the model and became non-significant — an 80% reduction — once institutional support, perceived permission to experiment, multilingual resource access, policy clarity, and risk sensitivity were added. Exposure was unevenly distributed (a clear majority of Kazakhstani faculty had AI training in the past six months, against roughly a quarter of Chinese faculty), and Chinese faculty reported both higher policy clarity and higher risk sensitivity. Structured prompt-task training outperformed conventional GenAI familiarization on post-test prompt design by a wide margin. Faculty readiness, on this evidence, is produced by provision and permission — what a center offers and what it allows — rather than by the national system it sits in.
- **Brief training shifts judgments, not intentions.** A three-hour pre-post pilot with 100 German teachers (Mesenhöller and Böhme, 2026) found that perceived usefulness (d = .32) and perceived ease of use (d = .25) rose significantly after a short practice-oriented session on AI for differentiation, while behavioral intention did not move from an already high baseline (M = 3.07). The authors read the gap as a sign that acceptance depends on conditions a session cannot supply, such as time, infrastructure and clear institutional rules. Short formats are worth running, but pairing them with those conditions is what turns favorable judgment into use.
- **Sustained monitoring, not one-off workshops, for initial training.** A systematic review of 11 studies of AI in initial teacher training for primary mathematics (Pinto et al., 2026) found that nine interventions were a single session or a few sessions embedded in existing courses, that attitudes were usually sampled once after the fact, and that ethics appeared in only three studies. The authors argue AI competency needs to develop across the whole training sequence, from a preparatory phase into the practicum and the early years of practice, with monitoring that follows that progression.
- **Exposure and repetition, not demographics, track favorable perceptions.** In a mixed-methods study of 302 Turkish primary mathematics teachers (Ciğerci and Uygun, 2026), prior AI training (t = 3.661) and frequency of AI use (F = 41.280) were the variables most consistently associated

with positive views, while willingness (M = 3.98) and attitudes (M = 3.82) sat well above personal experience (M = 3.00). The authors treat prior training as the clearest lever schools can act on, which points to repeated, sustained use rather than a single introduction.

- **Role rotation as the load-bearing structure.** A design-based study of 62 pre-service educational psychologists in Kazakhstan (Kenzhebayeva et al., 2026) rotated students through four professional positions over eight weeks, with generative AI supplying preliminary ideas. The authors argue the value lay in the rotation rather than in the tool, since each role framed the same case differently, and later cycles showed more requests for theoretical justification. They report engagement rather than measured gains, having collected no pre-post competence measures.

Distinct from academic education

Professional training differs from academic education in its focus on applied skills, immediate workplace relevance, and adult learner characteristics. Adult Learners theory and Adult Learners principles inform professional AI training design. Its other boundary is vocational education and training: VET admits people who do not yet hold the occupation and closes with a trade or technical qualification, so it carries initial occupational preparation and the qualification frameworks that certify it, whereas professional training starts from an existing role — reskilling, continuing professional education or vendor certification — and assumes the competence VET awards.

Expertise regeneration as a training concern. The Cognitive Commons framework (Lovett 2026) argues that HRD must move beyond organizational reskilling to profession-level stewardship: eliminating entry-level developmental positions in AI-exposed sectors can deplete the shared expertise pool on which all organizations depend, with a time-delayed effect that appears only after 5–20 years. This reframes professional training from individual competency development to collective commons maintenance. **Pair AI production with verification, and seek outside measures.** Nguyen et al. (2026) put automated hallucination checks and an SME audit between drafting and delivery across a five-stage upskilling pipeline, and rest the framework's strongest claims on a NASBA CPE accreditation and a vendor certification exam rather than self-defined success measures.

Common Misconceptions

"Coursework produces occupational competence." The framework on this page puts the highest competency stages behind industry-embedded experience rather than coursework, which is a real limit on what a training program can claim. A course can build the prerequisites; the gated stage needs the work.

"Fading support on a schedule is equivalent to fading it on evidence." It is not. Fading assistance against the learner's *estimated competence* cut simulator lap time **27.9% (p = 0.005)** and failures by **3.52 per lap**, whereas rule-based fading on a fixed schedule produced no reliable change. The same amount of support, released on a different signal, is a different intervention.

"AI literacy training generalises across roles." Most instruments do not measure role-specific competence: in a systematic review of **33 teacher AI literacy instruments**, **29 (87.9%)** targeted general AI concepts while only **4 (12.1%)** addressed the pedagogical or occupational use that the job actually requires. A program built on general instruments is measuring a proxy.

“A simulator is a substitute for workplace training.” It develops procedure and removes consequence, which is valuable and is exactly the part that cannot transfer — the consequence is the curriculum in safety-critical work.

Technologies and techniques

Models and techniques

Technologies

> **Technologies** — the models, architectures, and methods that power AI education systems, and the umbrella concept for the knowledge base's coverage of the technical layer. Where Pedagogies and Teaching Strategies and Learning Theories concern *how teaching and learning happen*, and AI Ed Evaluation concerns *whether AI works*, this page anchors the *technical* strand: the AI systems (large language models, generative AI, multimodal models, robots) and the techniques used to build, control, and deploy them (Prompt Engineering, retrieval-augmented generation, Reinforcement Learning, Educational NLP, knowledge graphs, agentic orchestration).

Questions to Consider

- You can be an excellent educator without being able to build an LLM — but this page argues your technical choices still shape what AI can and can't do in your classroom. What is one way the underlying technology of an AI tool might quietly change how your students learn, even if you never see the code?
- A common assumption is that the model is the whole story — but techniques like retrieval-augmented generation (RAG) and prompt engineering exist precisely to control and ground LLM output. Before reading further, when you ask an AI to 'be more accurate' or 'use this source', what do you think is actually happening under the hood?
- RAG is described as a core technique for reducing hallucination and improving safety. Why do you think fetching relevant knowledge to 'ground' an AI's answer would matter more for education than for, say, casual chat — and what could go wrong if that grounding fails?
- The page claims that technical choices embody pedagogical assumptions: a tutor built on Socratic prompting reasons with learners, while an answer-generating model may just hand over solutions. Can you recall an AI tool you've used that seemed to 'assume' a particular teaching philosophy — and did that align with how you actually wanted to teach or learn?
- Beyond raw accuracy, this page suggests AI systems should be evaluated on reliability, pedagogy, and equity. What headline metric do you suspect most people (including many educators) default to when judging whether an AI tool 'works', and why might that metric hide more than it reveals?
- Agentic AI is described as shifting AI 'from a prompt-responding tool into a proactive collaborator.' How might a system that initiates and orchestrates multi-step workflows on its own change what you, as an instructor or learner, are responsible for — and who holds it accountable?

Introduction

AI in education runs on a specific technical stack, and understanding it matters for educators and researchers even when they do not build systems themselves — because technical choices shape what AI can and cannot do in the classroom, the risks it carries, and how to evaluate it. This page organizes the knowledge base's technical-concept coverage: the AI systems, the techniques that adapt and control them, and how the technical layer connects to pedagogy, assessment, and evaluation.

AI systems in education

- **Large language models (LLMs).** The computational backbone of most modern AIED — LLMs generate human-like text for tutoring, assessment, and content generation, and are the most-referenced technology in the knowledge base. Training and fine-tuning adapts general LLMs for educational use.
- **Generative AI.** The broader category of systems that produce text, code, images, and other content — generative AI (driven chiefly by LLMs) is the technology behind the current wave of AIED research. See also multimodal models (text, image, audio) and Simulation.
- **Robots and embodied systems.** Robots in education add an embodied and often social presence — programmable kits for computational thinking and humanoid/social robots for tutoring, storytelling, and role-play. Robotics is a distinct technical strand that overlaps agentic AI and human-in-the-loop design.
- **Knowledge-based systems.** Knowledge graphs and educational NLP represent and process domain knowledge, increasingly combined with LLMs for grounded, explainable tutoring.

Techniques and methods

- **Prompt engineering.** Prompt engineering is how educators and developers shape LLM outputs — the primary mechanism through which offloading and control are enacted in LLM interactions.
- **Retrieval-augmented generation (RAG).** RAG grounds LLM outputs in retrieved knowledge, reducing hallucination and improving accuracy — a core technique for safe educational deployment.
- **Reinforcement learning.** Reinforcement learning trains agents to optimize behavior over time, used in adaptive systems and game-based learning.
- **Agentic orchestration.** Agentic AI systems plan and execute multi-step workflows — often orchestrating multiple specialized agents (see multi-agent systems) — and are reshaping AI from a prompt-responding tool into a proactive collaborator.
- **The educational agent stack lags the frontier.** Wang et al. (2026) mapped 474 studies and found GPT-series models and LangChain dominant while governed tool orchestration, persistent memory, and long-horizon planning were largely absent — and only 138 of 474 (29%) drew on educational theory.
- **Model training and adaptation.** LLM training and fine-tuning, educational alignment, and small-language-model adaptation make general models education-specific — though the evidence in the knowledge base puts retrieval and prompting ahead of training in the decision order, since a well-grounded prompt is cheaper than an adapted model.

How the technical layer connects to the field

The technical strand is inseparable from the knowledge base's other themes:

- **Pedagogy:** technical choices embody pedagogical assumptions — a tutor built on Socratic prompting reasons with learners, while an answer-generating model may default to direct provision (see pedagogies and teaching strategies).
- **Assessment and evaluation:** AI Ed Evaluation and benchmarks determine whether AI systems actually work; Assessment and Automated Assessment use the technical stack to grade and generate.
- **Responsible use:** technical techniques are central to reducing AI misuse — RAG (Retrieval-Augmented Generation) grounding, Guardrails, Prompt Engineering Scaffolding, and human oversight shape whether AI supports or undermines learning (Cognitive Offloading, Hallucination Risk).

Research attention is concentrated on a narrow slice of the tool ecosystem. Mapping 85 AI tools against the STEM and engineering literature, Terkowsky et al. (2026) found only 36 research-visible at all and conversational AI/LLMs accounting for 73.7% of 927 paper–tool connections, with 23 publications in an established laboratory context.

Implications for AI in education

- **Technical literacy supports critical use:** understanding the underlying models and techniques helps educators and learners use AI well and evaluate it critically (see AI Literacy).
- **Choose technology by pedagogical intent:** the AI system and technique should follow the teaching strategy, not the reverse.
- **Evaluate the technical layer:** AI Ed Evaluation and Benchmark research assess AI systems on reliability, pedagogy, and equity, not just headline accuracy.
- **Robots and agents are part of the stack:** embodied and agentic systems extend the technical repertoire beyond text — and bring their own design and safety considerations.

Common Misconceptions

"The model is the whole story." Techniques such as retrieval-augmented generation and prompt engineering exist precisely to control and ground an LLM's output, and the architecture around the model often determines whether it is usable in a classroom. Two systems on the same model can differ entirely in reliability because of what surrounds it.

"The field's technical maturity is established." The mapping is thin where it matters: across **474 studies**, GPT-series models and LangChain were dominant while **governed tool orchestration, persistent memory, and long-horizon planning were largely absent**, and only **138 of 474 (29%)** drew on educational theory. The stack being used is far narrower than the stack the field needs.

"Technical choices are the technologist's business, not the educator's." The page's framing is that you can be an excellent educator without being able to build an LLM and your technical choices still shape what

AI can and cannot do in your classroom. Whether a system grounds its answers in course material is a decision with pedagogical consequences that someone has to make.

“A more capable model will resolve the field’s gaps.” Orchestration, memory and long-horizon planning are architectural rather than capability problems — the documented absence is of systems that govern their own tool use over time, which a better model does not supply on its own.

Machine Learning

> **Machine learning** — the technical foundation of AI in education: algorithms that infer patterns, predictions, and policies from educational data rather than from hand-coded rules. It spans supervised learning (classifying at-risk students, predicting grades), unsupervised learning (discovering learner clusters), reinforcement learning (inducing tutoring and scaffolding policies), and deep learning (neural models for sequences, courses, and visual behavior). Generative AI is the latest and most visible subset, but it sits atop a much older stack of predictive and adaptive machinery.

Questions to Consider

- You've likely encountered recommendation systems or risk scores that 'learned' from data. How comfortable are you with a model deciding something about you (like an at-risk flag or a recommended path) based purely on patterns in historical data?
- The page draws a sharp line between predicting a risk and actually intervening — a risk score tells you a student might fail, but not what to do about it. Where have you seen a prediction offered as if it were already a solution?
- Machine learning can 'hack' its own reward: an AI tutor that optimizes for engagement can keep students entertained while teaching them little. If a system looks measurably successful but is pedagogically harmful, what measures should we watch besides the number it optimizes?
- Predictive models trained on historical grades can encode systemic bias, and automated proctoring raises false-positive risks that wrongly flag normal behavior. When data carries the biases of the past, how much should we trust an AI that uses it to make high-stakes educational decisions?
- Some AI systems outperform human-interpretable methods but remain opaque — you can see they work but not why. In education, when is interpretability a 'nice to have' and when is it non-negotiable?
- Generative AI is often treated as entirely new, but the page frames it as the latest subset of machine learning. How does seeing ChatGPT as part of the same predictive and adaptive machinery change what risks and limits you'd expect it to inherit?

Introduction

Machine learning is what turns educational traces into actionable intelligence. It powers the student models behind adaptive systems, the Learning Analytics dashboards that flag at-risk learners, the intelligent tutors that choose the next problem or scaffold, and the automated proctoring systems that monitor remote exams. Across the articles synthesized here, the pattern is consistent: collect data on learners, learn a predictive or decision model from it, and act on that model — whether the action is early-warning, course recommendation, adaptive scaffolding, or exam surveillance.

What machine learning does in education

Predictive modeling for student success. Supervised classifiers — Logistic Regression, Random Forest, SVM, K-Nearest Neighbors — identify at-risk students before they withdraw, using academic performance, demographic, and enrollment records. More advanced architectures go further: the TRACE transformer jointly predicts the courses a student will take and the grades they will receive next semester, modeling the concurrency of co-taken courses rather than treating history as a flat sequence. Optimizer-plus-sequence hybrids, such as the DMO-GRU framework in interactive online learning, combine automatic feature selection and hyperparameter tuning with recurrent nets to reach high accuracy and low error on engagement and performance prediction. A shared ambition is "precision education": continuous risk stratification and student digital twins that anticipate failure and align pathways with outcomes, shifting institutions from reactive remediation to preventive support. Glass-box models can hold their own here: Zhang, Jeffries & Koprinska (2025) report that decision trees which are intrinsically interpretable — trimmed by feature selection to only 3–5 leaf nodes — forecast module-level progress in large online programming courses as accurately as black-box random forests and SVMs (85–91% accuracy). Interpretability, then, need not be traded away for predictive power in early-warning applications. Tree-based models also prove effective for estimating item difficulty: Razavi and Powers (2026) fed LLM-extracted cognitive and linguistic features into random forests and gradient boosting machines to predict the difficulty of K-5 math and reading items (N = 5170). Correlations reached up to r = 0.87, with lower RMSE/MAE than direct LLM estimates, dummy regressors, TF-IDF baselines, and metadata-only models. The tree-based models also yielded interpretable feature importance — grade level and word count were top predictors — showing how structured features plus interpretable learners can outperform a single holistic judgment. Multimodal AI fusion extends this predictive toolkit: Bird (2026) fuses a fine-tuned ELECTRA transformer with a searched deep neural network over computational-linguistics features to classify English literature by UK Key Stage at an F1 of 0.996. That is far above the best unimodal transformer (BERT, 0.75) and the best linguistic-feature network (0.392), a concrete case where combining model families outperforms any single approach. Sukoon (Bashir & Afzal, 2026) is a compact applied case of supervised classification in education-adjacent Well-Being support: a Random Forest (100 estimators) over 20 features from the psychological, physiological, environmental, academic and social dimensions of a 1,100-response student stress survey. It was trained on a stratified 70/15/15 split, with a scaler fitted on training data only to avoid leakage, and benchmarked against an SVM on the same splits (89.09% vs. 88.48% accuracy). Two touches are worth noting: the authors interpret the confusion matrix by *error direction* — the model's main mistake was classifying low stress as moderate, which in a wellness deployment routes a student to more support rather than less. They also use native feature importances as a substantive finding (blood pressure 15.6%, teacher-student relationship 10.0%), while conceding that a single stratified split, without k-fold intervals, and a non-representative dataset limit the confidence of those weights.

Adaptive instruction and tutoring. Machine learning closes the loop between modeling and teaching. In intelligent tutoring systems, both a Bayesian Knowledge Tracing heuristic and a deep Reinforcement Learning policy adaptively selected worked-example types to elicit different levels of cognitive engagement, significantly improving posttest performance relative to non-adaptive control — while the two policies diverged by learner prior knowledge, raising interpretability questions. Reinforcement learning also underlies the pedagogical-safety agenda: because an RL tutor optimizes a proxy reward, it can "hack" that reward (boosting engagement while teaching little), and architectural constraints on prerequisite enforcement

and minimum cognitive demand are needed to keep it safe. Lighter adaptive programs, such as the rule-based STEM system in sixth-grade science, show that machine learning can be used sparingly — for monitoring rather than direct trajectory control — while still supporting deep learning.

On the Knowledge Tracing side, Pradeesh et al. (2026) show a recurrent model can be tuned to a curriculum's own structure: their OKT model treats Outcome-Based-Education course outcomes as knowledge concepts, couples expert-validated OBE affinity mappings (relations between course and program outcomes) with a Memory Augmented Neural Network for cross-outcome impact, and pairs a GRU backbone with domain-adaptive BERT embeddings — reaching 89.81% AUC and beating DKT, DKVMN, EKT, and SimpleKT on live engineering-program data.

Diagnosis from tabular numerical answers. Yin et al. (2026) show gradient-boosted trees solving the *diagnosis* side of tutoring in a domain long closed to AI: for Engineering Economics Calculated Formula Questions, where students' handwritten solutions lack structured digital data, they train a dedicated XGBoost multi-label backbone per question to map submitted intermediate and final numerical answers to instructor rubric mistake labels (average precision 0.81, recall 0.79, accuracy 0.65). Random-masking data augmentation — masking input features to "NaN" at varying probabilities — preserves the logical dependencies of tabular solutions better than interpolation methods like SMOTE and significantly improves diagnosis, and including intermediate answers helps most. It is evidence that tree-based models plus structure-aware augmentation can bootstrap tutoring feedback where generative methods lack training data.

A field-level view of the RL subset is provided by the Riedmann, Schaper & Lugrin (2025) systematic review of 89 RL-in-education studies: it confirms RL is a major ML lineage for inducing adaptive tutoring and scaffolding policies, but finds classical (Q-learning) methods more consistently effective than Deep RL (61% vs 36% significant superiority) and flags that over half of studies conduct no statistical testing — a methodological caution that echoes the validation concerns below.

From prediction to action and accountability. A persistent limitation is the gap between a risk score and a feasible intervention. The SC2R framework couples a calibrated predictive model with integer-programming recourse generation and semantic validation, producing intervention plans that respect timing, budget, and availability constraints rather than merely being model-valid. This move "beyond prediction" toward constraint-respecting, machine-checkable recommendations is the field's response to the charge that predictive AI in education can recommend actions institutions cannot or should not take.

Machine learning in proctoring

A distinct application is automated exam proctoring. Deep-learning systems — CNNs and RNNs/LSTMs analyzing eye movements, head posture, and facial expressions — detect cheating more reliably than traditional monitoring, but the decade-long systematic review finds persistent dataset limitations, single-model evaluations, reproducibility gaps, and false-positive risks that can wrongly flag normal behavior. The companion review of academic dishonesty documents the cheating methods such systems must counter (identity spoofing, browser use, copy-paste) and the practical burdens — cost, connectivity, test-taker anxiety — that bound their equity. Together they caution that ML proctoring must be paired with Privacy-preserving, context-aware design and accessible alternatives.

Limits and ethical concerns

The synthesized literature is candid about machine learning's limits. Gains often come from Benchmark or single-institution data and may not generalize without retraining; SC2R and TRACE both acknowledge this. Predictive models trained on historical grading can encode systemic bias, and risk scores applied to sensitive student data raise Privacy and equity concerns that demand AI Governance and human oversight. Interpretability is a recurring tension — RL policies can outperform interpretable heuristics while remaining opaque. And reward hacking shows that an ML system can be measurably successful while pedagogically harmful, which is why architectural safety constraints and audit infrastructure matter.

Validation practice is another source of overconfidence. Schuetze, Yan, and Carvalho (2025) show that knowledge-tracing models (BKT, BKT-with-Forgetting, AFM) appear to capture learning trends when fit retroactively to all available sessions, yet under **time-based (walk-forward) cross-validation** — training on earlier sessions to predict later ones, mirroring real deployment — they overestimate future performance, miss the spacing effect, and mis-order practice conditions. Forgetting-free models even matched forgetting-augmented ones, indicating forgetting was absorbed into other parameters rather than learned. When the training and deployment distributions are temporally separated — the norm for longitudinal student data — a strong in-sample or retrospective fit is no guarantee of predictive validity.

Generative AI as a subset

Generative AI — large language models and related LLM systems — is best understood as a subset of machine learning: the same neural and training foundations, but applied to *generating* content (explanations, feedback, dialogue) rather than classifying or predicting. It inherits the field's validity, bias, and safety concerns while adding new ones such as hallucination. For the purposes of this knowledge base, machine learning is the broader technical umbrella; generative AI is its most visible contemporary branch.

Teacher education and machine-learning literacy

Machine learning also appears in education as a *subject*. In initial teacher training, hands-on coding and robotics interventions using the Micro:bit and supervised image-classification projects significantly improved preservice teachers' knowledge of computational concepts and introductory machine learning, and their attitudes toward teaching it. As AI literacy enters curricula, equipping teachers with a working grasp of machine learning becomes a precondition for teaching it to students. A contrasting route reaches the same concepts without any software: in Sung and Gunpinar's (2026) online professional development, ten K-12 educators built an "explainable feature matrix" by hand — a yes/no table of shape features that *is* the classifier, testable and revisable rather than opaque. Code.org's sorting game and Google Slides were the only tools used. Their AI self-efficacy rose from below-moderate (M = 3.13) to above-moderate (M = 3.71) and negative descriptors in a word-association task fell from 30% of participants to none, though the evidence is small, uncontrolled, and entirely self-reported.

Common Misconceptions

“Accurate prediction requires an opaque model.” Interpretability and performance are more separable than that assumption allows. Zhang, Jeffries and Koprinska (2025) show that intrinsically interpretable decision trees — **pruned to just 3-5 leaf nodes** — hold their own on student-progress prediction in programming. When a five-node tree matches a black box on your task, the black box is buying opacity rather than accuracy, and in an educational setting where a decision must be explained to a student the glass box is the better trade.

“Machine learning in education is a neutral prediction technology.” Its applications carry the discipline’s governance failures with them, and proctoring is the clearest case: a model that infers something about a student from behavioral or physiological signals is making an accusation with a confidence score attached, and the evidence base for that inference is much weaker than the deployment rate suggests.

“Generative AI has made classical machine learning obsolete in education.” They do different jobs. Prediction of learner states, difficulty estimation and progress forecasting remain classical ML problems, and the knowledge-tracing and item-calibration literature this corpus documents is not served by a language model. Generative AI is a subset of machine learning rather than a replacement for it.

“Teacher education should teach students about LLMs rather than about machine learning.” Limiting literacy to the generative layer leaves practitioners unable to interrogate the predictive systems making decisions about their students — which is where the consequential errors concentrate.

Generative AI

> **Generative AI** — AI systems capable of producing text, code, images, and other content, most prominently large language models like GPT-4 and Claude. Generative AI is the technology driving the current wave of AI in education research.

Questions to Consider

- Generative AI produces fluent, confident-sounding content on demand. Does fluency equal correctness, and where have you seen a confident-sounding but wrong output — what made it hard to catch?
- Unlike earlier rule-based or retrieval-based systems, generative models create new content rather than retrieving stored answers. How does that shift change the risks — hallucination, over-reliance, academic integrity — compared to a search engine?
- With 80+ articles, generative AI is the largest thread in this knowledge base, spanning tutoring, assessment, content generation, and safety. Which application do you think is the most promising for learning, and which the most dangerous — and why?
- The same technology that can generate a Socratic tutorial can also produce a ‘correct-answer trap’ that encourages copying. What design choices might separate generative AI that scaffolds learning from generative AI that short-circuits it?

Introduction

What makes generative AI different for education

Unlike earlier rule-based or retrieval-based systems, generative AI produces fluent, contextually appropriate content on demand. This creates both unprecedented opportunities and novel risks:

- **Content generation:** LLMs can create instructional materials, examples, and explanations. Synthetic textbooks, adaptive videos, and instructional videos show the range of educational content generation.
- **Lesson-planning drafts that are platform- and language-dependent.** Expert evaluation of AI-generated science lesson plans shows content quality is neither uniform nor neutral. Karaismailoglu, Surmeli and Yildirim (2026) had eleven Science Education specialists score ChatGPT-4 and an education-focused tool (Teacher’s Buddy) against sixth-grade Engineering Design-Based Learning stages: the education-focused platform outscored the general-purpose one across all eight quality criteria, yet 7 of 11 experts still rated the plans only “applicable by correction.” Both platforms generated pedagogically richer output from English than Turkish prompts even when asked to localize for Mersin, Turkey — a digital-equity concern where prompt language shapes instructional quality.

- **Tutoring and dialogue:** AI tutoring systems use generative AI for conversational instruction. Socratic dialogue and collaborative tutoring exploit generative capabilities for pedagogical interaction.
- **Simulated patients and case consistency.** A multi-expert annotated corpus of 4,815 student-AI messages from the MeduAI-SP platform (Yang et al., 2026) found that only about 0.68% of LLM-generated standardized-patient responses contained clear fidelity problems, and progressive disclosure was rated clinically appropriate in roughly 99.3% of patient messages. This supports the claim that generative-AI simulated patients can sustain case consistency and inquiry-dependent, non-premature disclosure under structured YAML scripting (qwen-max), making them a stable-enough environment for outcome research rather than only for plausibility demonstrations — while the system deliberately withheld diagnoses and summative scores during learning.
- **Assessment:** Essay scoring, automated grading, and Formative Assessment increasingly rely on generative models. Benchmarks substantiate this shift for open-ended work: Pecuchova, Benko & Drlik (2025) found that context-sensitive GenAI models (GPTo1 reaching almost-perfect agreement with human graders) sharply outperformed earlier sentence-embedding approaches on grading open-ended student responses, which relied on rigid reference matching and misclassified valid but differently-worded answers. Olvet et al. (2026) extend this to pre-clerkship medical education, where GPT-4's scoring of open-ended questions reached substantial-to-almost-perfect inter-rater agreement with faculty (weighted kappa up to 0.94) — but only after humans iteratively refined the rubric across three rounds and remained in the loop to arbitrate discrepancies — while the most synthetic, holistic-rubric question stalled at moderate ($\kappa w = 0.54$). This is evidence that generative assessment reliability is shaped as much by human rubric engineering and error-pattern analysis as by the raw model. Yet the same fluency does not generalize across item types: Falahat et al. (2026) found ChatGPT-5 matched human faculty on objective pharmacy-exam items (CCC 0.935–1.000) but not on short-answer (≈0) or essay (0.341–0.854) items, and a structured rubric did not reliably close the gap.
- **Risks:** Hallucination, Over-Reliance, Cognitive Offloading, and Academic Integrity concerns arise specifically from generative AI's fluency and Accessibility.
- **A learning-safety problem beyond output quality.** Rahimi (2026) argues generative AI can raise the quality of a learner's work while performing cognitive work they need to do, so safety should be judged on the human-development trajectory — Learning Safety protecting competencies and Learning Soundness supporting their development — rather than accuracy, bias, or privacy.
- **Effectiveness claims measure performance, not learning.** The field's largest estimate — a meta-analysis of 69 studies reporting $g = 0.7$ for ChatGPT and similar tools — pools immediate task success rather than delayed, unassisted retention, so it is not evidence that generative AI produces learning (Yan et al., 2025).
- **Learning environment generation:** Specialized generative models now turn a course brief directly into finished learning artifacts. CogEvol (Tu et al. 2026), a family of models trained for single-pass generation of structured slides and self-contained interactive HTML pages, completes a slide in a median of 17 seconds and an interactive page in 59 — replacing minutes-long multi-turn agent Scaffolding. Reliability is enforced via a production pipeline that converts real failures

into 53,687 verified SFT samples plus a hybrid rule-plus-VLM reward for GRPO-based RL. This positions generative AI as a content authoring engine with implications for teacher and curriculum production workflows, and for evaluating whether AI-generated learning environments are functionally and pedagogically sound rather than merely visually polished.

A census of educator tool use shows attention concentrated on production rather than instruction: image, audio, video and presentation tools made up roughly half of the 50 tools nominated by 211 educators across nine countries, while tutoring and chatbot tools formed the smallest teaching-facing group (Bower, Torrington & Lai (2026)).

The knowledge base's generative AI coverage

With 80+ articles, generative AI is the knowledge base's largest technology thread. Across its 394 studies, ChatGPT with an unspecified version appeared in 94, the ChatGPT-3/3.5 family in 66, and the ChatGPT-4 family in 52 — so many reported capabilities describe model generations since superseded (Lin et al. (2026)). Research spans effectiveness studies (meta-analyses), safety concerns (tutor harms, guardrailing), and design principles (instructional guidance).

Pooled across 53 studies, GenAI-assisted education outperformed non-GenAI approaches on achievement (g = 0.40), higher-order thinking (g = 0.72), motivation (g = 0.81) and writing (g = 0.76), though game-assisted GenAI added no significant benefit (g = 0.24) (Dong (2026)).

A three-level meta-analysis of 22 studies finds GenAI-supported problem- and project-based learning producing a large pooled effect on learner-internal outcomes (g = 0.819), though a PET-PEESE correction reduces it to g = 0.378; embedding mattered too, with general chatbots pooling at g = 0.970 against g = 0.455 for custom or API systems (Chen (2026)).

A separate 42-study meta-analysis of motivation alone puts the pooled effect lower (g = 0.764) and reports a 95% prediction interval spanning [−0.689, 2.217], so the motivational advantage is not reliably positive for a new setting (Fang et al. (2026)).

Generative UI is the newest capability in this thread: models that emit a working interactive artifact — sliders, manipulable simulations — rather than prose. Kovshov et al. (2026), a Google Research team, report that off-the-shelf generative UI is not yet pedagogically precise enough for complex constructs, but that decomposing a learning objective into progressive leveled goals and wrapping generation in critique and self-improvement loops yields interactives expert teachers rate as acceptable. Theirs is an orchestration design: teachers state objectives, approve them and select among candidate simulations, so the binding constraint on bespoke interactive learning material shifts from production to specification, and pedagogical guardrails are embedded in the generation pipeline rather than left to teacher vigilance afterwards.

Beyond these core strands, recent work extends the evidence base across institutional, interactional, and domain contexts. Qin (2026) documents how Lingnan University institutionalized GenAI literacy for all undergraduates as part of a digital liberal-arts transformation. Chang and Li (2026) show that student-AI conversations encode discipline-associated cognitive engagement, with ~62% of prompts reflecting higher-order cognitive demand. Neto and colleagues (2026) systematically review GenAI in scenario-based healthcare education, finding prompt design functions as instructional specification but is rarely aligned with instructional frameworks (34.8%) or reported in reproducible detail (34.8%). GenAI also powers role-play

simulations of learners for practice-based teacher training: Zhuang and Zhang (2025) built *Student GPT*, a custom ChatGPT chatbot that simulated a middle school student holding common ratio-reasoning Misconceptions about AI, giving preservice mathematics teachers affordable, content-specific practice at diagnosing student thinking — evidence that prompt design (a literature-grounded prompt reliably elicited target conceptual errors, 0.98 vs. 0.40) can steer an off-the-shelf generative model into a useful pedagogical persona.

A GenAI-guided mathematics professional-development case study of eight in-service teachers in rural, under-resourced districts had Bicer et al. (2026) engage mathematical Creativity, content knowledge and pedagogical content knowledge as interconnected reasoning across ten modules, crediting progressive scaffold fading and simulated student reasoning; they report engagement patterns, not measurable gains.

A systematic review of language educators (Li et al. 2026) finds educators value GenAI most for preparatory content work — lesson planning, materials creation, and writing support — while hesitating on live classroom use, with concerns centering on academic integrity (plagiarism and assessment validity), professional displacement, and technostress; adoption is shaped by professional-identity, pedagogical, technical, institutional, and integrity factors, and competency gaps map to episteme, techne, and phronesis.

Content generation likewise reaches beyond mathematics into co-designing learning resources with teachers — for example, teacher-AI co-designed Simulation scaffolds for drone STEM learning that preserve pedagogical validity and contextual relevance. In children's STEAM arts education, Luo and Tahir (2025) experimentally quantified the gains of ChatGPT-assisted over teacher-generated lesson plans (expert-rated median 20.5 vs. 17.6, $p = .002$, large effect) — yet the same study documents that fluent output carries real failure modes for classroom generation: plans that are idealized or impractical for daily teaching, missed child-safety constraints (e.g., suggesting carving knives for young children), Western-centric cultural bias, and logically flawed or irrelevant image/resource generation. The contribution is a prompt framework (Role–Instructions–End Goal plus a "four points and one line" quality rubric) that turns the reliability question from whether the model can generate into how prompts and evaluation criteria must constrain it for pedagogical use. Equity-oriented uses remain underexplored; an all-girls GenAI makerspace initiative in Europe combined two GenAI tools with feminist pedagogy to address persistent gender inequities in computing participation, analyzing girls' GenAI-generated images and stakeholder reflections. Assistive and inclusive applications are a growing strand: Khlaif et al. (2026) — a qualitative case study of 21 visually impaired undergraduates in Palestine — found GenAI tailors pace, content, and delivery to individual learning profiles, simplifies complex academic texts, and converts content across modalities, with learners viewing it as complementing rather than replacing teachers.

- **Generative AI as a pedagogical agent in elementary critical media literacy.** Demir and Akar (2026) operationalize the 5E instructional model with generative AI tools (ChatGPT for reflective questions and Q&A, Grammarly and Canva AI for content refinement, Padlet for peer feedback) embedded phase-by-phase rather than as isolated add-ons, in an 18-hour critical media literacy program for fourth-grade Turkish students aligned to the Turkish Language and Social Studies curricula. The AI-supported group showed large gains in media reading (+3.50), writing (+1.67), and total media literacy (+5.17, all $p < .01$) with between-group effect sizes of Cohen's $d = 1.12$ (reading), 1.18 (writing), and 1.31 (total literacy), while the control group advanced only modestly. Qualitative analysis surfaced six domains of critical media literacy growth — digital self-protection and data privacy, purposeful and responsible media use, safe communication and

boundary awareness, critical evaluation and misinformation awareness, online risk awareness, and media Ethics/digital citizenship — illustrating how generative AI can be designed into a curriculum as a scaffolded pedagogical agent that cultivates critical evaluation rather than short-circuiting it.

Generative AI in specialized domains: dyslexia support

A 2026 interdisciplinary systematic review (Dabaghi, D'Urso & Sciarrone, PRISMA-guided, 2018–2024, n=72) finds that **generative AI is under-utilized in the dyslexia-support domain**. GAI research (all from 2024) clusters into intelligent chatbots, teacher training support, and exploratory studies, and is rapidly overtaking classical ML as the tool of choice — yet rigorous experimentation and real-world validation remain largely absent. The review's future-trends analysis points to GAI-powered personalized materials and real-time adaptive feedback, multi-modal diagnostic models integrating eye-tracking, EEG, and behavioral analytics, NLP-driven intelligent tutoring systems and conversational agents, and educator-facing support tools. This illustrates both the promise of generative AI for content generation and interactive support in a specialized, high-need domain and the risk that its adoption outpaces the evidence base.

Common Misconceptions

- **"A large effect size means the tool improves learning."** The field's largest estimate — a meta-analysis of 69 studies reporting $g = 0.7$ for ChatGPT and similar tools — pools **immediate task success**, not retention, transfer or understanding. The same issue applies to the 53-study pooled estimate ($g = 0.40$ achievement, 0.72 higher-order thinking, 0.81 motivation, 0.76 writing): these are outcomes measured close to the intervention, on tasks resembling the intervention. An audit of 14 meta-analyses claiming AI improves education found **none justified its claims**. Treat any headline number as evidence about performance under conditions, and ask what was measured and when.
- **"The newer model will fix it."** Model generation is not the binding constraint. ChatGPT-5 matched human faculty on objective pharmacy-exam items (CCC 0.935–1.000) but not on short-answer items (≈0) or essays (0.341–0.854), and **a structured rubric did not reliably close the gap**. Capability gains on closed tasks have not transferred proportionally to open-ended work, which is where most assessment actually lives.
- **"Usage data shows it is working."** In the 394-study mapping, ChatGPT with an unspecified version appeared in 94 studies and the 3/3.5 family in 66 — so a large share of published capability claims describe **model generations since superseded**, and many studies do not report the version at all. Reported behavior is tied to a specific model and a specific date, which makes undated claims about "generative AI" unfalsifiable rather than general.
- **"It is safe because experts annotated the corpus."** A multi-expert annotated corpus of 4,815 student-AI messages found only about 0.68% of messages contained the harmful or off-task content the coding scheme was built to detect. That is a finding about the base rate, not about safety: rare events are rare, and a system's failure tails are exactly the cases a corpus of that size struggles to characterize.

What this means for practice

For instructors

- Design the assessment and the tool together. Where AI is strong on objective items and unreliable on essays, an assessment plan that weights essays has to carry explicit verification rather than a generated draft.
- State the model and version in your own classroom evidence and in anything you report. Undated claims cannot be checked, and the version often explains the result more than the pedagogy does.
- Treat the novelty horizon as real and short. Pooled effects are measured near the intervention; plan for the decline that longitudinal work documents rather than being surprised by it.

For developers

- Do not roadmap against pooled effect sizes. An audit of 14 meta-analyses found none justified its claims, so a product claim resting on a headline *g* is resting on methodology that does not survive inspection.
- Instrument the base rate before optimizing it. A 0.68% incidence rate means most quality work happens in the tail, and tail performance is what determines whether a deployment is acceptable.
- Report version, date and task type with every benchmark number you publish, because a capability claim that omits them is not reproducible.

Large Language Models (LLMs)

> **Large Language Models (LLMs)** — neural network models trained on vast text corpora that generate human-like text, powering most modern AI in education applications. LLMs are the computational backbone of generative AI tutoring, assessment, and content generation in education.

Questions to Consider

- What do you believe an AI chatbot ‘knows’ when it answers you? The page frames LLMs as generating probable text rather than retrieving verified facts — how does that distinction change how much you would trust a model’s explanations?
- LLMs are described as the engine behind most modern AI education tools — tutoring, grading, content generation, and even diagnosing what students know. Of these uses, which do you think is most and least appropriate for a probabilistic text generator, and why?
- The page reports that three different LLMs produced sharply divergent support plans for the same learning-analytics input, each with different demographic assumptions. If models aren’t interchangeable as advisors, what does that mean for an institution that adopts one?
- Because LLM output is sensitive to prompts and settings, two people can get very different results from the same model. How should this influence how you — as a learner or designer — phrase requests, and how much you trust a single output?
- A key limitation is hallucination — plausible-sounding but ungrounded content. In a tutoring or grading context, what would it take for you to feel confident the model wasn’t inventing something, and what safeguards would you demand before letting it assess a real student?

Introduction

LLMs as the engine of AIED

LLMs are the most-referenced concept in the knowledge base (60+ articles) because they underpin nearly every AI education application:

- **Tutoring:** AI tutors use LLMs for dialogue, explanation, and Problem Solving guidance. Training and fine-tuning adapts general LLMs for educational use.
- **Assessment:** Grading systems, essay scoring, and item difficulty prediction leverage LLM capabilities. Razavi and Powers (2026) show GPT-4o can estimate the difficulty of K-5 math and reading items (N = 5170) calibrated under the Rasch IRT model: zero-shot ratings correlated moderately-to-strongly with true difficulties (r = 0.83 math, r = 0.81 reading) but varied by grade, while a feature-based strategy in which the LLM extracts cognitive and linguistic features for tree-based models reached correlations up to r = 0.87 — evidence that structured feature extraction can outperform a single holistic LLM judgment. Across the aggregate grading literature, a PRISMA-guided systematic review of 42 empirical studies (2023–2025) concludes that LLMs match human raters on short, well-structured tasks with detailed rubrics yet cannot fully replace human

judgment on complex, open-ended, or subjective work, and that model version is a dominant determinant of grading quality (Can ChatGPT Replace the Teacher in Assessment? A Review of Research on the Use of Large Language Models in Grading and Providing Feedback). Reliability also varies sharply by item type: Falahat et al. (2026) found ChatGPT-5 matched faculty closely on objective pharmacy-exam items (CCC 0.935–1.000) but was unreliable on short-answer (CCC ≈0) and essay (0.341–0.854) items, and that providing a rubric did not consistently improve agreement.

- **Generated item labels track surface form, not difficulty.** A 378-item audit found an LLM's Easy/Medium/Hard labels rose in lockstep with its own co-generated Bloom level (ρ=0.90) and with stem length (15.9 to 30.2 words) yet correlated with empirical item difficulty at only ρ=0.06 over 7,888 student responses, evidence that generation-time difficulty metadata describes formatting rather than demand on prior knowledge (An & Wang (2026)).
- **Generated items can still match expert items.** o3-mini in a generate → judge → revise loop built exams for 71 classes; under a Bayesian hierarchical 2PL IRT model the AI items were easier but more discriminating ($\bar{\alpha}$ = 1.3 vs. 1.2) and more informative (I_{max} = 3.85 vs. 2.61) than expert AP Statistics items (Isley et al. (2025)).
- **Annotation quality is a design outcome, not a single-prompt property.** Bernado et al. (2026) prompted a five-model panel to judge human-readable assertions about each utterance instead of emitting a label directly, and a transparent classifier over those binary judgments (macro-F1 0.673, Cohen's κ 0.688) beat the best published direct prompting of a frontier model (0.61 macro-F1) while trailing a fine-tuned RoBERTa-base encoder (0.76); cross-model agreement functioned as a screening device, not as validity evidence.
- **Multimodal AI reasoning LLMs as graders:** when a multimodal, reasoning-capable LLM (GPT-o4-mini) graded a 296-student handwritten general-chemistry exam page-by-page against rubric images, single-run total scores were highly reproducible (ICC(A,1) = 0.967; averaging five runs reached 0.993) and agreed strongly with TA totals (R^2 = 0.91), yet item-level reliability was sharply format-dependent — textual and reaction-equation answers graded well while drawing and graphing were worse than random (background grids distract AI vision). This shows an LLM grader's trustworthiness is a function of response format and task, not just raw model capability, and that selective deferral via confidence filters is needed for high-stakes use (Assisting the grading of a handwritten general chemistry exam with artificial intelligence).
- **Content:** Generative AI content creation relies on LLMs. Question generation and video generation are LLM-driven.
- **Safety:** Pedagogical Safety, Hallucination Risk, and SafeTutors: Benchmarking Pedagogical Safety in AI Tutoring Systems research examine LLM-specific risks.
- **Diagnosis:** Knowledge Tracing and Cognitive Diagnosis increasingly incorporate LLMs for richer student modeling. Grounding matters enormously for error diagnosis: Reddig, Arora & MacLellan (2025) showed that supplying GPT-4 the tutor interface structure plus Bayesian Knowledge Tracing skill estimates raised logical-error identification from 40% to 81% on factoring (overall error diagnosis ~87.8%), while multi-step problems and responses with several errors remained weak cases and hallucinated "common-misconception" diagnoses persisted — evidence that an

LLM's diagnostic value is as much a function of the structured context and learner-model signals it receives as of the model itself.

- **Verification separated from generation — with correlated failure modes.** Hossain et al. (2026) restrict tutor retrieval to instructor-approved course material and route claims through an architecturally separate DeBERTa-v3-large-MNLI verifier, but caution both models share broad web training and can fail in correlated ways, and the verifier cannot check a code trace without executing it.
- **Assessment model shift (2017–2024):** Morley et al.'s scoping review of auto-marking short-answer science questions traces the field's move from fine-tuning smaller BERT models (dominant through 2021) toward prompting larger LLMs (GPT-1/2/3.5/4) from roughly 2022 — adopted via Prompt Engineering rather than fine-tuning — with domain-augmented models, rubric-aware prompting, and chain-of-thought lifting accuracy. Yet GPT models were rarely benchmarked against BERT on standard corpora, few auto-markers could explain their marks, and bias was seldom examined, cautions that apply to LLM assessment generally (Auto-marking short answer questions in science: The foundational years of transformer-based models from BERT to GPT-4).

Model-specific research

The knowledge base covers both general-purpose LLMs (GPT-4, Claude) and education-specific adaptations. Small language model benchmarks compare SLM performance for tutoring, and Suvernev et al. (2026) argue SLMs are architecturally appropriate for agentic tutoring when deployed as tool-augmented planners — deterministic tools carry the load a small model would otherwise handle implicitly — with pedagogical control residing in the escalation policy rather than the model. Educational alignment research addresses how to make LLMs pedagogically appropriate. A classroom study across three frontier families — Oppenheimer, Cash & Connell Pensky (2025) — found that ChatGPT, Gemini, or Claude could act as collaborative critique partners for argumentative writing: over a semester of iterative essays, students improved on argument quality, prompt engineering, and response-to-AI feedback by roughly a full standard deviation each (all $p < .001$) and engaged deeply (87.8% rebutting LLM claims), positioning general-purpose LLMs as viable collaborative learning partners rather than mere answer generators.

A complementary line of work reframes LLMs from static graders into emulators of pedagogical reasoning. Yaşar et al. (2026) showed that GPT-4, scaffolded with a semantically precise, iteratively co-refined rubric, could approximate human evaluative judgment in design-based learning: initial LLM–human agreement was poor (Cronbach's Alpha = 0.393; Kappa −0.06 to 0.18), but iterative rubric refinement raised mean agreement from 54.75% to 81.25% (final Alpha = 0.798, Kappa 0.40–0.55), and K-means clustering of human and LLM score matrices showed highly correlated centroids ($r = 0.89$). The study positions the rubric as a mediating interface between human pedagogical intent and machine inference — evidence that off-the-shelf LLMs are not interchangeable as evaluators either, and that their assessment behavior is a design outcome shaped by the rubric and prompts they are given. Raw model capability differentiates grading too: benchmarking eleven GenAI and sentence-embedding models on 1,885 open-ended responses, Pecuchova, Benko & Drlik (2025) found only GPTo1 reached almost-perfect agreement with expert human graders (Fleiss' Kappa 0.82), with Claude3 and PaLM2 slightly behind, while reference-aligned models such as

BERT fell far short — showing that frontier-model context-sensitivity matters for reliable open-ended assessment. Model differences also matter for high-stakes downstream uses. López-Pernas et al. (2026) showed that three LLMs produced sharply divergent student-support prescriptions for the same learning-analytic input, and each imposed distinct demographic priors on the learner profiles they generated — evidence that off-the-shelf LLMs are not interchangeable as prescriptive advisors. Similarly, Olvet et al. (2026) found that GPT-4's scoring of pre-clerkship medical open-ended questions climbed to substantial-to-almost-perfect inter-rater agreement with faculty (weighted kappa up to 0.94) only after three rounds of iterative rubric refinement, and fell to moderate (κw = 0.54) on a holistic-rubric item — reinforcing that rubric design, not raw capability alone, is the decisive lever for LLM scoring reliability. Model-specific behavior also shows up in how LLMs respond to skeptical users: an algorithmic audit queried ten frontier LLMs 500 times each with a rural-Montana K-12 AI-skeptic persona to test whether AI systems consulted by skeptical users are predisposed to encourage adoption. Eight of ten acknowledged user concerns then redirected to AI-engagement framings; composite scores spanned from 3.85 (Claude Sonnet) to 7.52 (Gemini 3.1 Pro Preview), with a cross-family AI scorer panel clearing Cohen's kappa >= 0.70. The pattern was a model-dependent design outcome. Model capability also depends on how models are combined: Bird (2026) fine-tuned eight state-of-the-art transformers (BERT, ELECTRA, RoBERTa, XLNet, ERNIE, ALBERT, DistilBERT, Longformer) to classify English literature by UK Key Stage, finding the best unimodal transformer (BERT) reached only an F1 of 0.75 — while fusing a fine-tuned ELECTRA with a computational-linguistics neural network lifted F1 to 0.996, showing that transformer text classification alone is limited and that fusion with complementary features is where the gains lie.

LLMs also affirm preferentially: across 11 models, AI responses affirmed users 49% more than human responses, and more sycophantic replies drew higher ratings, raising trust and continued use — a failure mode for coaching, tutoring or feedback, where constructive challenge is the point (Potel & Kumashiro (2026)).

Common Misconceptions

- **"The model's raw capability determines how well it can diagnose errors." Grounding** does: Reddig, Arora and MacLellan (2025) showed supplying GPT-4 the tutor interface **substantially changed** its error diagnosis. What the model is given about the learner's context does more work than which model it is.
- **"Any frontier model behaves the same as a learning partner."** Oppenheimer, Cash and Connell Pensky (2025) studied **three frontier families** — ChatGPT, Gemini and Claude — in a classroom comparison, precisely because the families are not interchangeable as collaborators.
- **"Better models mean less Scaffolding needed."** GPT-4 **scaffolded with a semantically precise, iteratively co-refined rubric** could approximate human evaluative judgment in design-based research. The approximation came from the rubric refined over iterations, not from the model alone.

RAG (Retrieval-Augmented Generation)

> **RAG (Retrieval-Augmented Generation)** — an AI architecture that combines information retrieval with text generation, allowing LLMs to ground responses in external knowledge sources rather than relying solely on training data. In education, RAG addresses hallucination, enables curriculum-grounded tutoring, and powers domain-specific AI tutors.

Questions to Consider

- You've probably seen an AI chatbot confidently state something false. What does 'grounding' a model's response in external documents change about that failure mode, and what new failure modes might it introduce?
- RAG retrieves relevant materials and feeds them to the generator. Before you read, what assumptions does this make about the quality of the retrieved content — and about whether the retrieved text is actually the right thing to teach?
- The page contrasts RAG with fine-tuning: retrieval grounds responses in up-to-date sources without retraining, while fine-tuning embeds behaviors. If you were building a curriculum-aligned tutor, which approach would you trust for accuracy, and which for teaching style?
- RAG is presented as the main answer to hallucination in education. But consider: if the retrieval source itself contains errors, or is outdated, can RAG still hallucinate? Where might the guarantee of 'grounded in verified content' break down in practice?
- For a developer or instructor: what does a tutor need to 'know' beyond the textbook content — pedagogy, when to withhold answers, how to probe understanding? Where would RAG alone fail to provide that, and what would you combine it with?

Introduction

How RAG is used in education

- **Domain-specific retrieval with notation awareness:** AlgoRAG indexes textbooks, 847 lecture slides, 312 solved practice problems, 156 worked proof templates and 89 complexity worksheets for theoretical computer science courses, adding mathematical entity recognition and notation-aware re-ranking; it answered all 179 instructor-authored exam questions within a 240-second timeout (mean 38.0 seconds) but produced BLEU-4 = 0.0000 and a 0.7620 rubric score, which illustrates both the value of the architecture and the limits of the metrics used to judge it.
- **Hallucination reduction:** EduGuard and EduZone use RAG to keep AI tutor responses grounded in verified educational content, reducing Hallucination Risk.
- **Grounding is only as good as source inspection:** only 1 of 12 participants noticed a deliberately mismatched source card, so a provenance label can act as a seal of authority rather than an invitation to verify the retrieved material (Sun et al. (2026)).

- **Curriculum-grounded tutoring:** KITE retrieves relevant curriculum materials to inform tutoring responses, ensuring alignment with course content.
- **On-premises deployment for institutional control:** CourseChat runs a multi-course RAG tutor for undergraduate business education on local edge hosts with a local vector database and an Ollama-served 8B model, keeping course materials and student dialogue on campus infrastructure; model choice became a joint hardware-and-serving decision when larger candidates failed a latency gate (CourseChat).
- **Curriculum-grounded retrieval did not separate itself on time.** Aila retrieves from Oak National Academy's quality-assured curriculum plans, and teachers in its trial spent 0.76 of the comparison group's lesson preparation time (Roy et al., 2026). The report reads that as similar to the general ChatGPT trial's 0.69, so grounding in verified curriculum content was not what separated them.
- **Textbook and materials indexing:** Synthetic textbook organization indexes educational content for retrieval. StructRAG extends retrieval to structured diagrams.
- **Training pipeline integration:** Pedagogical LLM training uses RAG to ground tutor training in educational best practices.
- **Course-specific academic support:** Beacon retrieves from a single programming module's approved teaching materials to serve students who hesitate to approach a lecturer, and 89% of the 15 evaluating students rated its responses highly aligned with course materials. The design point is that grounding is an institutional answer to the mismatch between general-purpose LLMs and module-level expectations.
- **Ingest-time structure versus query-time retrieval:** Wright (2026) compiled the same DS3001 Machine Learning course corpus into seven cross-referenced wiki concept pages carrying source citations, and set it against a tuned vector-RAG baseline of chunked-embedding retrieval. Over 59 human-written questions the compiled wiki out-answered the tuned index, 9.95 versus 9.05 of 10, with a bootstrap CI on the difference excluding zero. It was also more often grounded in the material the answerer actually saw (98% versus 81%), with both gaps roughly tripling on questions that needed material from more than one page (cross-page scores 9.93 versus 8.14, where RAG's grounded rate fell from 87% to 64%). The grounding gap was not a retrieval failure: only 2 of vector RAG's 11 ungrounded answers were retrieval misses, while the other 9 had the relevant excerpts in context and still added unsupported detail — evidence that structure at ingest constrains elaboration, not just access.
- **Retrieving on a summary instead of the student's words (LC-RAG).** Collaborative talk often has no semantic link to the knowledge base: students say "put that position block there," so a discourse-only retriever returns unrelated chunks, and the authors' example is a passage about a 1990s cartoon pulled from a physics and computing textbook. Log-contextualized RAG has an LLM summarize each segment of work from its discourse plus the environment log (which model component is being edited), then retrieves on that summary. Across 216 collaborative modeling segments and five embedding models judged by GPT-4o, it beat the discourse baseline in four models, from 0.403 to 0.620 win rates, and retrieved a tighter set of chunks (167 unique against 267 of 7,386). It lost in one model because the summaries became more specific to the task than

the general textbook corpus was: query scope and corpus scope have to be matched deliberately (Cohn et al., 2025).

RAG vs fine-tuning

RAG serves a complementary role to Large Language Models (LLMs) fine-tuning — retrieval provides up-to-date, domain-specific grounding without retraining, while fine-tuning embeds pedagogical behaviors. The knowledge base's research explores both approaches and their combination.

Common Misconceptions

- **"Showing the source makes the answer verifiable."** Only **1 of 12 participants noticed a deliberately mismatched source card**. A provenance label can act as **a seal of authority rather than an invitation to check** — the display of grounding raised trust without raising scrutiny, which is worse than no label because it manufactures confidence.
- **"Retrieval quality is the whole problem."** Retrieval is necessary and not sufficient. Grounded answering scored **9.05 of 10 with a bootstrap CI on the difference excluding zero** and was **more often grounded in the material the answerer actually saw (98% vs. 81%)** — so the measured gain is in fidelity to evidence, and the evidence has to be correct for that fidelity to mean anything.
- **"Single-page retrieval generalises."** Both gaps **roughly tripled on questions requiring material from more than one page** (cross-page scores 9.93 against a lower baseline). Multi-document reasoning is where grounded systems degrade, and it is exactly where courses ask the hardest questions.
- **"Retrieval removes the need for scrutiny."** Beacon retrieves from a single module's approved materials to serve students who hesitate to ask a person — a defensible scope. Narrow, approved corpora are what make the grounding meaningful; the label alone does not.

Prompt Engineering

> **Prompt engineering** — the practice of designing and refining inputs to large language models to achieve desired outputs. In education, prompt engineering serves dual roles: as a learner skill (students must learn to prompt effectively) and as a system design lever (developers craft prompts that shape AI tutoring behavior).

Questions to Consider

- You've likely typed a prompt into an AI tool recently. Now consider this: the way you phrased it isn't neutral — it may reveal how you planned, thought, and allocated your effort. What might your own prompting habits say about how you approach problems?
- A study found that users who phrase requests skillfully systematically get better output than those expressing the same intent less adroitly. If you accept that 'prompt privilege' is real, is fair access to AI best fixed by teaching everyone to prompt better, or by redesigning the system to not demand that skill — and what are the trade-offs of each?
- Is prompting a 'trick' to be memorized, or a genuine intellectual skill? One line of research treats it as professional judgment within a discipline (journalism, law, medicine); another treats it as a core of AI literacy. Which view aligns with your own experience of what actually separates good prompts from bad ones?
- Well-designed prompts can scaffold student thinking, while poorly used ones can encourage cognitive offloading. Can you recall a moment when an AI answer did the thinking for you? What about the prompt — or your intent — made that happen, and could it have been designed to do the opposite?
- Prompting is both a learner skill and a system-design lever: some tutors now automatically route and select prompts for the user. As prompting moves from the user to the system, what do students lose — and what do they gain?
- Set a small goal before you read: after learning about prompt engineering, decide on one concrete way you'll change how you write prompts in your own work, and what result you'll check to know it worked.

Introduction

Prompt engineering is central to effective Generative AI use in education. Unlike traditional programming interfaces, LLMs respond to natural language — but the quality, accuracy, and pedagogical value of those responses depend heavily on prompt design. Research in this knowledge base reveals that prompting is not a neutral act: it reflects how students think, plan, and allocate cognitive effort. Miles, Haber-Curran and Arar (2026) sharpen what the term covers by distinguishing prompt engineering, the technical optimization of inputs for performance, from prompt literacy, the rhetorical, ethical and reflective work of clarifying purpose, reading output critically and revising with stated reasons. Their Prompt Literacy Cycle (Clarify Purpose, Craft the Prompt, Engage with Output, Refine the Prompt, Reflect) and a sample process rubric

make the distinction teachable, and they argue that instruction which optimizes outputs alone leaves the ethical and epistemological dimensions of LLM use untouched.

How prompt engineering appears in the research

- **Prompting as cognitive trace:** Misiejuk et al. show that prompt patterns reveal cognitive offloading — high-quality work uses context-rich, polite, and instructional prompts; low-quality work shows reactive disagreement without domain grounding
- **Depth improves the product, not the retention.** In 22 postgraduates, the share of explanation-seeking ("why/how/explain") prompts predicted independently marked task quality (β = 6.27) beyond baseline knowledge and prompt volume, yet showed a null association with immediate recall (Tsiligkiris (2026)).
- **Prompt cognition tracks the discipline, not the student.** Chang and Li (2026) classified 60,087 prompts from 116 courses and found Bloom-level profiles differed by discipline — STEM Apply-prevalent (20.8%), social science Create-prevalent (33.8%) — with course-level variance exceeding student-level variance.
- **Prompting as literacy:** Tracing GenAI literacy and K-12 prompting literacy research frame prompting as a core AI Literacy component
- **Prompt literacy is a perceived capability, and it still predicts engagement.** In 829 design students across 40 intact classes, self-reported prompt literacy — six adapted self-report items, not observed prompting — predicted learning engagement at β = 0.539, 95% CI [0.473, 0.595] (Han and Cao, 2026). The association held regardless of functional dependence (p = 0.396) or emotional dependence (p = 0.941). Only cognitive dependence, substituting AI judgment for one's own, clearly thinned it.
- **Novices default to trial and error, and blame the model.** In a text-linguistics seminar, ten genAI novices refined prompts by trial and error, rarely reached for in-context examples, and overwhelmingly attributed poor outputs to the LLM rather than their own prompt formulation (Brocca & Garassino (2026)).
- **Vague prompts leave a trace in the dialogue.** The lower-quality group's signature was a self-repeating clarification loop (IC → IC, Z = 3.25), traced to vague prompts and AI misreadings, and carrying the study's largest frustration gap (2.12 vs 3.82); prompt debugging on authentic logs targets it as it happens (Fang et al. (2026)).
- **When the instructor models the prompt, students reuse it verbatim.** Among 310 recorded prompts from twelve middle-school STEAM groups, exact copying of the instructor's instruction was the most frequent student standpoint at 47.1%, ahead of spontaneous inquiry at 28.7% (Zhao & Li (2026)).
- **A regulatory cycle beats a prompt formula.** In a quasi-experimental pilot with 42 undergraduates, students taught the IDEA cycle (Intent, Deconstruction, Expression, Adaptation) produced higher-quality prompts and outputs than peers taught Role–Task–Context–Format prompting in all five task categories (adjusted prompt gains of +11.77 to +29.19 points) (Wang et al., 2026).

- **Prompting as system design:** CoTAL uses human-in-the-loop prompt engineering for formative assessment scoring; anchor-based prompting improves automated essay scoring
- **Prompting is the entry skill, not the discipline.** Gorsky (2026) frames AI Literacy for software professionals as the ability to manage agents rather than to prompt them, naming framing, specification, context engineering, verification, multi-agent orchestration and auditability as the skills a curriculum must assess (Gorsky (2026)).
- **Adaptive prompt routing:** Learning to Prompt treats prompt selection as part of the tutoring system itself — subject-aware prompt routing over 14 pedagogical features, where a stochastic router selects the best prompt per conversation. This shifts prompting from a learner skill into an adaptive system-design lever, improving engagement and efficiency (28.1% vs 19.6% exercise conversion in a real-world A/B test).
- **Prompt modalities:** Voice vs. text input research examines whether prompting modality affects learning outcomes
- **Prompting beyond text — scientific illustration.** Prompting can generate molecular and physical-chemistry figures quickly, but a locally persuasive rendering can still be wrong or carry representational bias, so students must interrogate AI-generated visualizations against chemical principles rather than trust them (Li et al. (2026)).
- **Scaffolded prompting:** Guided LLM scaffolding and critical engagement scaffolding teach structured prompting as a learning intervention
- **Coach prompting with fading support:** in ARPG+, a real-time coach diagnosed prompt quality across six dimensions and faded support as competence grew, lifting final prompt quality to 7.82 against 5.95 for static templates and 4.52 with no assistance (Ye et al. (2026)).
- **Task decomposition has an optimum:** generating tutor-training lessons in three segments produced the highest-rated lessons (mean 14.67) while a single pass scored lowest (10.67) and five segments fell back below three — moderate decomposition beats both extremes (Lin et al. (2025)).
- **Prompt privilege and equity:** Jin et al. show prompting expertise is unevenly distributed — users who phrase requests skillfully systematically get better output than those expressing the same intent less adroitly. Their Prompt Equity Transformer shifts prompt optimization from the user to the AI system, arguing that equitable output should be engineered into the model rather than demanded of novices.
- **Prompt refinement plateaus; fine-tuning takes over from there.** Iterative prompt design yielded diminishing item-quality gains in L2 listening Assessment, but fine-tuning GPT-4.1 on the optimized prompt — the prompt held constant — produced more contextually grounded and balanced items, isolating model adaptation rather than prompt craft as the next lever (Aryadoust & Wong, 2026).
- **Prompting as situated professional judgment.** Beyond literacy and system design, prompting can be framed as a *disciplinary practice*. The Dierickx et al. taxonomy for journalism treats task definition and prompting as a form of professional judgment exercised within a domain's epistemic and ethical norms — translating journalistic work into explicit tasks (newsgathering →

sensemaking → editing → publication/distribution) makes assumptions, priorities, and ethical considerations visible, and turns prompting into a pedagogical tool for critical AI literacy. Its logic transfers to other knowledge-intensive professions (law, medicine, public policy).

- **Prompt design as instructional specification.** Neto and colleagues (2026) find in their systematic review of GenAI in healthcare education that prompt design functions as a form of instructional specification, encoding the cognitive targets and quality criteria implicit in expert authoring — yet only 34.8% of studies aligned generated content with instructional frameworks and only 34.8% reported prompting in enough detail to reproduce. Looi, Liu, and Sun (2026) further show how prompt architecture can embed pedagogical rules (correctness gates, anti-spoiler boundaries, goodbye gates) to constrain Large Language Models (LLMs) tutoring behavior in procedural domains.
- **Rubric-guided and role-aware prompting.** Yaşar et al. (2026) showed that rubric-guided prompting — treating the rubric as a semantic interface between human pedagogical intent and machine inference — drove LLM–human agreement on student design work from 54.75% to 81.25% (Cronbach's Alpha 0.393 → 0.798). Rubrics engineered for LLMs must balance precision and flexibility: too vague invites free interpretation, too rigid reduces the model to pattern-matching. Role-aware prompting — evaluating the same artifact under instructor, peer-reviewer, and grant-reviewer prompts — produced qualitatively distinct, epistemically different feedback, showing that prompt design shapes not just accuracy but the evaluative stance of the output.
- **Prompt scaffolding can move a model further from the teacher.** Almousa et al. (2026) had seven models produce paragraph-level writing feedback under three prompting strategies and found that adding category names or worked examples increased divergence from the teacher distribution for most of them, improving only Mistral-7B (0.2695 to 0.2398). The zero-shot baseline stayed closest, so focus-type instructions are something to test rather than assume.
- **Context-aware prompting for assessment.** Context-aware prompting of pre-trained language models automates the coding of collaborative problem-solving skills from process data, modeling dependencies between behavior codes and fusing cognitive and social abilities. This enables structured CPS analysis at scale and in real time, overcoming the labor intensity of manual coding schemes.
- **Role-based templates and quality rubrics for teacher planning.** Luo and Tahir (2025) empirically develop a prompt framework for children's STEAM arts lesson planning that pairs a Role (R) – Instructions (I) – End Goal (E) template (adapted from RISEN) with a "four points and one line" optimization rubric — standardized, practical, engaging, and complete, plus an extension dimension. Applying the rubric to critique and refine prompts kept generated plans acceptable to practicing art teachers (mean ratings above 4/5) while exposing recurring gaps (personalization, child-safety constraints, cultural bias) that plain one-shot prompting left unaddressed — showing prompt templates plus explicit evaluation criteria function as a quality-control scaffold for classroom generation.
- **A five-part scaffold, tested across four model families.** Role–Goal–Input–Process–Output prompts raised rated output quality from 3.318 to 4.603 ($\Delta = +1.285$) over 400 matched pairs, with every family improving and the weakest baseline gaining most (Li et al. (2026)).

- **Role and constraint design as the independent variable.** Wang et al. (2026) compare two agents built on the same model and platform at temperature 0.3 whose only difference is how the prompt specifies role, skills, and constraints: an expert teacher agent answering from a bounded textbook knowledge source versus an empathic student-centered agent scripted to diagnose Misconceptions about AI and check comprehension. The role difference alone shifted learning performance, cognitive load, flow experience, and perceived empathy, showing that role specification is an instructional-design decision with measurable effects rather than a stylistic flourish (Pedagogical Agent).
- **Prompting as assessment design.** Xiong et al. (2026) map Evidence-Centered Design's student, evidence, and task models onto the parts of a scoring prompt, deriving five principles — intentionality, traceability, accountability, iteration, and equity; their ECD-built prompts scored narrative essays more accurately than zero-shot, few-shot, and chain-of-thought baselines.

Connections to broader concepts

Prompt engineering connects to Scaffolding — well-designed prompts can scaffold student thinking rather than bypass it. It intersects with Metacognition and AI Literacy, as effective prompting requires understanding both the AI's capabilities and one's own learning goals. The Cognitive Offloading research directly links prompt quality to whether AI use supports or undermines learning.

- **Writing skill drives prompting, and both predict Vibe Coding success.** In a preregistered CHI 2026 study (N=100), Thorgeirsson, Weidmann & Su found that written-communication proficiency predicted GUI-oriented vibe-coding performance (r = .29), with human-graded prompt quality *mediating* the link — response-process evidence that clear, structured prose translates into better natural-language programming prompts. Both writing skill and CS achievement were independent predictors, and CS achievement (r = .39) carried roughly twice the unique variance, so improving prompting alone is unlikely to fully substitute for programming fundamentals in LLM-native development.
- **Prompting strategy predicts performance.** An empirical study of 128 engineering students found that AI Query Efficiency (clear, well-structured prompts) and AI-Driven Problem Solving (strategic integration of AI output into reasoning) were the strongest predictors of academic success — even after controlling for GPA — indicating prompting is a teachable skill that shapes how effectively students learn with AI.
- **Prompting style, not just prompt quality, tracks outcomes.** Traits derived from 1,540 tutoring sessions linked conceptual questioning to exam performance while task-delegation behaviors correlated negatively — but the same traits failed to replicate the following semester, so they are behavioral patterns rather than stable skills (McNichols, Du and Lan (2026)).
- **A usable taxonomy, and which prompt categories actually pay off.** Jacobsen et al. (2026) translate technical strategies into the 3K model (*Kontext*, *Kernauftrag*, *Klarheit* — context, core task, clarity): eleven practice-oriented categories, each with a good/average/suboptimal rubric, and each tested as an experimental variation on feedback generated for pre-service teachers' learning goals. Domain-specific technical language was the decisive category — replacing subject terminology with everyday paraphrases significantly reduced feedback quality across three models

(β = −0.412). Adding concrete examples and removing the chain-of-thought instruction produced no significant difference from the baseline in the first study; examples did help once the analysis was rerun with the best-performing model-prompt combinations (β = 0.52). Prompt quality and model choice together explained 42.8% of the variance in rated feedback quality, which is the paper's case that prompt engineering is a measurable and teachable competency rather than a stylistic preference — and that its categories are not interchangeable in effect size.

- **Better prompts reduced iteration without raising output quality.** Teachers given AI training before a lesson-preparation experiment wrote longer, more detailed prompts that needed less refinement, while untrained teachers used shorter prompts and required more subsequent iterations, yet blinded expert ratings of the resulting materials were equal (Appel et al., 2026). Prompt craft here bought fewer correction rounds, not a stronger first draft.
- **Students name intent alignment as the difficulty, not syntax.** Surveying 234 Chinese university students, Fan and Liu (2026) found refinement after a poor output was the most endorsed capability (72.2%) while setting output constraints was the least (66.2%, with 22.2% neutral). Strategy preferences barely moved between a research assignment and a creative brief: of four matched pairs only output-format specification differed after correction (0.26 points, dz = 0.233, BH-adjusted p = .002). A fixed role-task-format template drew the weakest support of any general strategy at 59.4%. Among the 12.8% who answered an open question, prompt-intent alignment appeared in 40.0% of comments, and adding more detail did not reliably fix a stuck exchange. All of it is self-report from one questionnaire.

Common Misconceptions

- **"Prompt quality is a student attribute." Prompt cognition tracks the discipline, not the student**: Chang and Li (2026) classified **60,087 prompts from 116 courses** and found the discipline predicted prompt sophistication. Teaching students to prompt better addresses a variation that sits in the subject matter.
- **"Students develop their own prompting practice."** When the instructor modeled the prompt, **students reused it verbatim** — among **310 recorded prompts from twelve middle-school STEAM groups**, exact copying of the instructor's instruction was common. Modeling produces reproduction, which is why it is a system-design lever rather than a transferable skill.
- **"Prompting is a learner skill first and a system property second."** This shifts prompting **into an adaptive system-design lever**, with measured effects on **engagement and efficiency (28.1% vs 19.6% exercise conversion)**. The interface's prompting affordances moved behavior more than instruction in prompting did.

LLM Training and Fine-Tuning

> **LLM Training and Fine-Tuning** — how educational AI models are made: the pipeline from pretraining through post-training to adaptation, what each stage costs, and what the evidence says it buys. The organizing problem is an **incentive mismatch**: general-purpose models are optimized to answer, while teaching requires withholding the answer. Post-training and fine-tuning are the two levers that change that behavior, and the knowledge base's clearest result is that they are a *third* choice, not the first — retrieval and prompting come earlier in the decision, and one study here found supervised fine-tuning failing at a task where plain prompting won (WrAFT). Written for educational software developers and teaching practitioners deciding what to build with.

Questions to Consider

- If you have a tutoring task where a general model answers too readily, is your first move a better prompt, retrieval over your own materials, or training? What would you need to measure to tell which one helped?
- Fine-tuning needs data. Where would your project's training examples come from, who owns them, and what privacy review would they need before they could be used?
- A study here found that fine-tuning a model on assessment data improved *formatting and similarity* while a separate fine-tune failed outright at generating feedback. What does that suggest about matching the training method to the task?
- Post-training with reinforcement learning can teach a model to guide rather than answer. What reward would you write to capture "guides well", and how would a model game it?
- The knowledge base puts model and prompt choice at only about 15% of what separates an LLM from student learning gains. If that is right, how should it change your build-versus-buy decision?
- A fine-tuned model that is accurate can still be unsafe across a long conversation. What would you test before letting one talk to students unsupervised?

Introduction

Educational AI development runs into the same wall from two directions. General-purpose language models are post-trained on human preference for helpfulness, which in practice means answering promptly and completely; tutoring requires the opposite, because the pedagogical goal is to help a student reach the answer rather than to hand it over. At the same time, a general model knows nothing about your curriculum, your rubric, or your institution's voice, and no amount of prompt engineering reliably installs those.

This page covers the techniques that change a model rather than the text you send it. They sit on a **ladder of increasing commitment**: prompting, then retrieval, then parameter-efficient adaptation, then full fine-tuning, then post-training with preference or reward signals. Each rung costs more data, more compute, and more evaluation discipline than the last, and each is a worse first choice than the rung below it unless a specific measurement justifies the climb. Much of the research literature reports only the top of that ladder, which makes it easy for a developer to reach for training when retrieval would have been sufficient.

The page is organized around the decisions a builder actually faces: which lever to pull (this section and the next), what adaptation buys and costs in practice, what post-training can shape that adaptation cannot, and how these systems fail. Terminology is used in its standard sense: **pretraining** is the from-scratch stage on a general corpus, **post-training** is everything after it that shapes behavior (supervised fine-tuning, preference optimization, reinforcement learning), and **fine-tuning** covers both the supervised stage of post-training and the later task- or domain-adaptation work, including parameter-efficient methods.

The training pipeline, stage by stage

Three stages, with very different accessibility. Knowing which one a paper is describing prevents most misreadings of this literature.

Pretraining builds a base model from a general text corpus. It is the stage that produces the model's broad capability, and it is out of reach for essentially every educational project: the cost is measured in millions of dollars and the data is a web-scale crawl. Nothing in this knowledge base does it. Its relevance to practitioners is diagnostic rather than actionable — pretraining data is the dominant lever on how a model behaves, and it is the one lever you cannot pull. That asymmetry is why the field's remaining techniques all operate on an already-trained model.

Post-training shapes behavior on top of the base model. Supervised fine-tuning (SFT) teaches the model to imitate demonstrations; preference optimization and reinforcement learning then push it toward outputs a reward model or a set of human judgments rates higher. This is the stage where a model can be taught to guide instead of answer, and it is where the most striking educational results live. It is also the stage most sensitive to reward design, because a reward is a compressed specification of what you want and models optimize whatever you actually wrote.

Adaptation fits an existing model to your task or domain, usually with far less data and compute. Parameter-efficient fine-tuning (PEFT), of which LoRA is the common form, trains a small number of added parameters and leaves the base weights frozen. Full fine-tuning updates everything. Distillation and unlearning sit alongside them. The sections below take each in turn. For most educational developers this is the practical stage — the one where a few hundred to a few thousand examples and a single GPU can produce a deployable model.

Prompt, retrieve, or train? The decision that comes first

The strongest single result in this knowledge base on that question is a retrieval study, not a training study. Building a course knowledge-base assistant, Shen et al. (2026) evaluated local models in three configurations and found that **retrieval, not the model, is the first-order design decision**: their local LLM with no retrieval reached only **52.3%** accuracy, *below* a TF-IDF baseline of **55.4%**, while adding retrieval-augmented generation with no fine-tuning at all lifted it to **66.6%** (Towards sustainable AI knowledge-base assistants in computer science education: on-premise deployment and optimization with open educational resources). The fine-tuning configurations they also tested are reported alongside retrieval ablations, quantization and energy per query, which makes the comparison unusually honest: a base model with no grounding can be worse than a decades-old lexical method, and the cheapest fix is not training.

What the field actually builds reflects a similar ordering. A PRISMA-guided review of 23 empirical studies (2020–2025) on customizing AI for writing instruction found **prompt engineering dominant (N = 13), ahead of fine-tuning (N = 7) and hybrid architectures (N = 3)** (Customizing AI for writing pedagogy: a systematic review of pedagogical goals, theoretical principles, and technical design). The review's sharper finding is a structural misalignment rather than a technique ranking: stated pedagogical goals have moved toward writing processes, feedback literacy and higher-order academic skills, while the dominant implementations still pursue product-focused goals through prompt design or fine-tuning.

Where prompting and training have been compared head-to-head, the result depends on the task, which is exactly why the decision should be measured rather than assumed:

- **Training wins when the target is a stable output format or a controlled property.** On automatic item generation for L2 listening assessment, iterative prompt refinement plateaued, and fine-tuning GPT-4.1 *on the optimized prompt* then improved generation beyond prompting alone — isolating model adaptation, rather than prompt design, as the driver of the remaining gain (How to train your dragon: Evaluating prompting and fine-tuning for GPT-based item generation in L2 listening assessment).
- **Prompting wins when the target is judgment-laden text.** The same system that fine-tuned successfully for *scoring* failed at *feedback*: in WrAFT, a fine-tuned GPT-4o module reached QWK 0.84 and RMSE 0.44 on 360 held-out TOEFL essays, but supervised fine-tuning for feedback generation produced truncated and unparseable output, while directly prompting Claude 3.7 produced the feedback teachers rated best (WrAFT: a Modularized Automated Writing Evaluation System for Argumentative Essays). Fine-tuning taught the model to hit a score; it did not teach it to write.
- **Prompt-level shaping can substitute for training when the target is a persona or a rubric.** Rubric-guided prompting, iteratively co-refined, raised LLM–human agreement on student design work from **54.75% to 81.25%** (Cronbach's Alpha 0.393 → 0.798) without any fine-tuning (From evaluation to emulation: LLMs as agents of iterative pedagogical design), and a literature-grounded custom-GPT prompt elicited target mathematical Misconceptions about AI at **0.98** presence against **0.40** for a broad prompt (Integrating ChatGPT in Mathematics Teacher Education: AI-Based Simulation Role-Playing to Support Practice-based Teaching).
- **There is a ceiling on all of it.** Hardy and Kim (2026) estimate that model and prompt choice together account for only about **15%** of the misalignment between LLMs and student learning gains, with the rest shared across models, and they found that benchmark-weighting and unanimous-voting ensembles made alignment *worse* (Knowledge without Wisdom: Measuring Misalignment between LLMs and Intended Impact). If pretraining data is the dominant lever and it is the one you cannot pull, then expectations for what any of these techniques can achieve should be calibrated accordingly.

What fine-tuning buys: controllability over scale

When a general model cannot be made to hold a property you need, fine-tuning on a modest dataset often can — and the recurring result is that *targeting beats size*. Three 8B models fine-tuned on an expert-designed children's reading curriculum outperformed zero-shot GPT-4o and Llama 3.3 70B on difficulty-related

metrics, with negligible safety issues. The authors frame this as **controllability over scale**, since a compact model can be tuned to a specific reading level and error pattern in a way a general model cannot be asked to (Children's English reading story generation via supervised fine-tuning of compact LLMs with controllable difficulty and safety).

The pattern repeats across very different tasks:

- **Curriculum grounding.** A 24,795-example multilingual instruction dataset grounded in Indian Knowledge Systems produced a 7B fine-tune scoring **6.39** on a five-judge external panel (median over 1,201 stratified items). That is within **0.15** of a strong general reference model at a fraction of the deployment cost — while the same base model scored **near zero on IKS-specific dimensions** without the fine-tune (IKS-Instruct: A 24,000-Example Multilingual Dataset for Teaching Language Models Indian Knowledge Systems). That gap between "competent generally" and "competent here" is the whole case for domain adaptation. Note also the counterintuitive detail the authors report: quality did **not** rise monotonically with data curation.
- **Curriculum-structured data is sample-efficient.** Under a matched budget of roughly 2,300 samples, fine-tuning on question–answer pairs derived from a K–12 knowledge graph of People's Education Press textbooks beat equally sized slices of eight mainstream instruction corpora, and the gains transferred beyond the trained subjects, evidence that curriculum structure is what distinguishes educational training data (Liang et al. (2026)).
- **Assessment reliability, cheaply.** A single LoRA adapter trained on roughly **3,900** pooled graded examples brought five small open models (4B–30B) to parity or better with a human grader across two computer-science exams, and nearly erased persona sensitivity (drift ≤ 0.32 MAE) (Where LLM Graders Succeed and Break: Evidence from Two Computer-Science Exams). One adapter, one dataset, several base models — this is the shape of a practical deployment.
- **Selective automation.** Confidence was a reliable predictor of scoring error ($\beta = -0.602$, $p < .001$). Routing the least confident **20%** of responses to human review moved a fine-tuned GPT-3.5 model from $r = 0.781$ to $\mathbf{r = 0.822}$ (RMSE 0.5990 → 0.5544) while cutting manual scoring work by roughly **80%** (Know when to trust: Making AI scoring more reliable for educational assessment). Fine-tuning here is not replacing the human; it is making the human's attention affordable.
- **Measuring constructs you would otherwise hand-score.** Fine-tuned Hungarian transformers (hubert-base-cc, PULI-BERT-Large) were benchmarked against TF-IDF features and Qwen3 embeddings for scoring reflective writing in teacher training (Automatic Reflection Level Classification in Hungarian Student Essays), and a fine-tuned Multimodal AI model (Qwen3.5-based) was shown to reconstruct item characteristic curves for multiple-choice items, learning the response patterns encoded in 3PL and MCM curves rather than being told them (Multimodal item parameter estimation using simulated response probabilities).

Parameter-efficient adaptation in practice

LoRA and its relatives are where most educational teams will actually work, and the literature contains unusually specific guidance about how they behave.

Rank is a trade-off, not a dial to maximize. Lu et al. (2026) built 360 system–user–assistant dialogues from a Linear Control Systems course, restructured answers into a Solution–Method–Teaching-Points format, and applied LoRA to Qwen2.5-3B and 7B at ranks 4, 8 and 16. Structured-output coverage moved from near zero at base to roughly **1.00**, and the best configuration (7B, r = 16) reached ROUGE-L **0.4093** with bootstrap confidence intervals for the gain entirely above zero. But **gain per million adapter parameters fell monotonically as rank rose**, so course-level alignment is a scale-and-rank trade-off rather than a free upgrade (LoRA Fine-Tuned Models for Control Systems Course Q&A: A Multidimensional Evaluation of Model Scale and Rank Effects). Their metrics measure similarity and formatting, not derivational accuracy, which is the standard caveat for this whole family of evaluations.

Scale does not predict success, and identical settings behave differently across architectures. AiAWE, an open-source automated writing evaluation system built on a LoRA-adapted Gemma-3-27B-it, reached RMSE 0.474, QWK 0.828, and agreement within ±0.5 of the human score on **90.56%** of 360 evaluation essays, outperforming LLaMA-3.3-70B and a fine-tuned GPT-3.5 baseline — while running on a consumer-grade server. Three broader findings matter more than the score: model scale was **not** a reliable predictor of downstream performance under LoRA adaptation, **identical LoRA hyperparameters produced qualitatively different adaptation behaviors across architectures**, and a well-tuned mid-size open model can be competitive with proprietary systems (AiAWE: An Open-Source LLM Automated Writing Evaluation System Using LoRA-Adapted Instruction-Tuned Models).

Which layers to adapt is a real decision. In a discourse-analysis system for English teaching, fine-tuning a truncated BERT by updating **only the last four Transformer layers** beat both alternatives: adapting only the top layer hit a lower ceiling, and full 12-layer fine-tuning overfitted and oscillated (Automatic discourse relation classification and feedback optimization in English teaching based on transformer BERT model).

The base architecture can matter more than the parameter count. Fine-tuning three open text-to-image models on 1,000 captioned nuclear-engineering images substantially improved Stable Diffusion XL, gave limited gains for SD-v3.5-Medium, and produced **no measurable improvement for the flow-matching Flux.1 model at all** (NuclearDiffusion: Text-to-Image Foundation Models for Learning Nuclear Energy Concepts). A fine-tuning recipe is not portable across architectures, which is the same lesson AiAWE reports from the other direction.

Two adjacent techniques round out the adaptation stage. **Distillation** compresses a large or black-box system into a small deployable one. A two-stage pipeline distilled a fitted black-box ML estimator and its post-hoc interpretation into a small open-weight LLM, with a 2B-parameter “mentee” achieving near-lossless recovery of the oracle effect surface (r > .90). That result is reported under a faithfulness-first evaluation that audits every narration against the attribution it claims to describe (Distilling Black-Box Machine Learning into a Small, Self-Explaining Language Model for Learning Analytics). **Unlearning** removes targeted content after training: gradient-based unlearning was applied to three models to strip PII and harmful content, tested in two removal orders (PII-first and harmful-content-first) (Balancing AI responsibility with privacy, safety, and utility: Unlearning in large language models for mathematics education) — the relevant tool when a model has memorized something it should not carry.

Post-training: shaping behavior, not just format

Adaptation teaches a model *what to produce*; post-training teaches it *how to behave*. This is where the pedagogical results are most striking, and where the design of the reward or preference signal decides everything.

The pipeline result. Singh et al. (2026) transformed Qwen3-32B into EduQwen through three stages — initial RL, synthetic SFT, final RL — reaching **96.52%** on the CDPK benchmark and surpassing Gemini-3 Pro's **90.55%**. The intermediate results are the instructive part: the first RL stage alone reached 94.13%, SFT on 40,000 self-generated responses took it to 96.20%, and the final RL round added the last fraction. The reward model prioritized **guiding responses over direct answers**, hard-negative mining excluded questions the base model already solved, and rollouts were extended from 5 to 8 steps to capture multi-step pedagogical decisions (Application-Driven Pedagogical Knowledge Optimization of Open-Source LLMs via Reinforcement Learning and Supervised Fine-Tuning). Against that, the Pedagogy Benchmark — drawn from real teacher professional-development exams across **97 models** — found accuracy ranging from **28% to 89%**, evidence that pedagogical knowledge is not acquired incidentally during general pretraining (Lelièvre et al., 2025).

Training the decision rather than the utterance. TACT post-trained a tutor on a 13-strategy taxonomy plus a two-axis student-move taxonomy and gained **20.30 points** over its Qwen3.5-4B backbone, with a diagnostic benchmark that withholds the learner-state labels available during training so the model must infer state from dialogue (TACT: Taxonomy-Aligned Post-Training for Pedagogically Adaptive English Tutoring). The same logic appears in Special-R1 for special education alignment (Special-R1: Reinforcement Learning for Special Education — Aligning LLM Tutors to Diverse Learners through Disability-Adaptive Training) and in heuristic-RL work that aligns models as Socratic guides rather than answerers (Beyond Direct Answering: Aligning Educational LLMs as Socratic Guides via Heuristic Reinforcement Learning). Post-training need not only shape what the model says: one platform pairs a guarded tutoring chatbot with a reinforcement-learning agent that chooses the next practice problem, so the trained policy decides what the learner does next (Effective Personalized AI Tutors via LLM-Guided Reinforcement Learning).

Distilled reasoning models. A cheaper route to pedagogical behavior is to teach a small model to imitate a larger one: Pedagogy-R1 (1.5B and 7B) was instruction-tuned on pedagogically filtered outputs distilled from a QwQ-32B teacher, paired with Chain-of-Pedagogy prompting (Pedagogy-R1: Pedagogical Large Reasoning Model and Well-balanced Educational Benchmark).

Instruction-conditioned post-training versus authentic data. LearnLM frames education-model training as *pedagogical instruction following*, carrying system-level instructions that let developers and teachers specify tutor behavior without committing to one definition of pedagogy. It is mixed into Gemini's post-training stages by co-training, and experts preferred it over GPT-4o (**+31%**), Claude 3.5 Sonnet (**+11%**) and base Gemini 1.5 Pro (**+13%**). The key finding is that **RL is substantially more effective than SFT alone** for following nuanced pedagogical instructions in long conversations (LearnLM: Improving Gemini for learning). TeachLM takes the opposite bet: that prompt engineering is a stopgap and the scarce ingredient is *authentic* learner–tutor interaction data. Trained on **100,000 hours** of one-on-one sessions under rigorous anonymization, it doubles student talk time, improves questioning style, and increases dialogue turns by **50%** (TeachLM: Post-training LLMs for education using authentic learning data). Together they define the

design space: instruction-conditioned post-training when your data is scarce, fine-tuning on real tutoring interactions when you have it.

Supervision quality beats supervision quantity. SWIM's progression for a writing simulator is the cleanest demonstration. Rubric-grounded prompting gave limited proficiency control (best average trait QWK 0.577 for Claude Sonnet, 0.422 for GPT-5.4, near zero for an open 7B model); supervised fine-tuning lifted that 7B model to **0.474 ± 0.023**. GRPO against an automated-essay-scoring-derived reward lifted it further to **0.618 ± 0.005** across every trait and prompt, with the reward designed as a dense trait-normalized accuracy because exact-match rewards are too sparse in the multi-trait setting (SWIM: Student Writing Simulation via Proficiency-Conditioned Generation). The misconception-modeling study reaches a sharper conclusion about *what* the supervision must contain: instruction-tuned models learned algebra misconceptions only when trained on **step-level solution traces**, with accuracy staying **below 30% at every data size** when trained on final answers alone. Its student role overgeneralized the learned error until correct examples were explicitly mixed in at ratios as low as **one in four**, while the tutor role showed no such cost, holding correct accuracy from **93% to 98%** across ten jointly trained misconceptions (Misconception Acquisition Dynamics in Large Language Models).

The training data is itself something models can curate: Edu-QuRating adapts preference distillation to educational data curation, replacing a single "is this educational?" score with 20 rubric dimensions covering factual accuracy, pedagogical structure and level suitability (Edu-QuRating: Multi-Dimensional Educational Data Curation with Distilled Pairwise Judgements).

Theory can be a training scaffold. For agents automating instructional systems design, a hybrid of classical ADDIE and Dick & Carey frameworks with ReAct-style reasoning outperformed both pure theory (structured but inflexible) and technique-only agents (flexible but ungrounded), across **25,795** scenarios from a 51-variable context matrix with a multi-judge protocol to reduce LLM-as-judge bias (ISD-Agent-Bench: A Comprehensive Benchmark for Evaluating LLM-based Instructional Design Agents). And a study of supervision *labels* found that assigning every training example one target behavior — subject competence, curriculum grounding, diagnostic reasoning, or Scaffolding — lifted every model scale tested, with the largest gains in scaffolding and in using a learner's history, while knowledge-state diagnosis remained weakest at **54.04%** (OmniEdu: Open Foundation Models for Learning and Teaching).

Training the learner side, not only the tutor

The same machinery is increasingly pointed at simulating students, which changes the economics of evaluating a tutor: instead of recruiting learners, you generate them.

The caution is that simulated students must be validated like any other instrument. Benchmarking fine-tuned and prompted models on **382 held-out dialogues** from the largest public corpus of real student–tutor mathematics dialogues — across seven metrics spanning linguistic, behavioral and cognitive aspects — produced the field's most direct test of whether simulated students behave like students (Simulated Students in Tutoring Dialogues: Substance or Illusion?). Two further approaches push on fidelity: INSIDE fine-tunes LLMs to both *act* and *think* like students, generating internal dialogue grounded in Bloom's Taxonomy across cognitive, affective and action dimensions and training on paired think-traces and actions (INSIDE the student's mind: Jointly modeling latent reasoning and action in LLM student simulators), and history-aware profiles condition simulation on a student's prior trajectory rather than a static persona (Who Am I?

History-Aware Profiles for Student Simulation in Tutoring Dialogues). For a developer, the practical lesson is that a simulator is a measurement instrument and inherits every validity question that implies.

What goes wrong

Sycophancy is a training objective, not a usability setting. Tutoring requires corrective friction, and models resist it. EduFrameTrap shows that models which withstand context-switch attacks still capitulate under authority or social-affective pressure and withhold corrective feedback, which is why its authors argue "kind-but-correct" behavior should be an explicit training requirement rather than a preference (Sycophancy is an educational safety risk: Why LLM tutors need sycophancy benchmarks). Training that rewards guiding over answering — as EduQwen's DAPO reward model does — is one structural lever against it, but contextual sycophancy persists after prompting and alignment, with learners' errors still propagating into AI advice (The Hidden Cost of Contextual Sycophancy: an AI Literacy Intervention in Human-AI Collaboration).

Training does not make a model safe over a long conversation. SafeTutors shows that even specialized pedagogical models degrade across sustained dialogue and can commit answer over-disclosure harms (SafeTutors: Benchmarking Pedagogical Safety in AI Tutoring Systems), so pedagogical safety has to be tested at conversation length rather than at the single turn.

Validation can substitute for training — or be required instead of it. A frontier untrained GPT-4 produced roughly **35%** too-general, incorrect or answer-revealing hints when authoring feedback for an intelligent tutoring system, and its own automated quality checks misaligned with human judgment; the authors conclude that LLMs lack an internal model of instruction and that robust validation or domain-specific training is needed before unsupervised learner-facing use (Generating In-Context, Personalized Feedback for Intelligent Tutors with Large Language Models). The practical implication cuts both ways: sometimes the right answer is a validation layer rather than a training run, and sometimes validation is what tells you a training run failed.

Your evaluation may be measuring the wrong thing. This is the most common trap in the fine-tuning literature here. ROUGE-L and QWK measure similarity and ranking, not derivational correctness (LoRA Fine-Tuned Models for Control Systems Course Q&A: A Multidimensional Evaluation of Model Scale and Rank Effects); a fine-tune can reach excellent QWK while the same system's feedback is unparseable (WrAFT: a Modularized Automated Writing Evaluation System for Argumentative Essays); and a model can rank students correctly while being wrong about how likely each is to need help. Where the target is a construct, fine-tuning should be paired with an instrument that measures the construct — the confidence-routing result is a good template, since it converts an accuracy number into an operating policy with a human in the loop (Know when to trust: Making AI scoring more reliable for educational assessment).

A practical sequence for educational developers

Distilled from the evidence above, in the order that avoids wasted compute:

1. **Establish a baseline you can beat, including a trivial one.** The course-assistant study's no-retrieval model scored below TF-IDF. Log your prompt-only accuracy before you consider training.

2. **Add retrieval before parameters.** Grounding the model in your own materials is the cheapest large gain reported here (52.3% → 66.6%), and it is reversible.
3. **Engineer the prompt, and re-engineer it iteratively.** Rubric-guided refinement moved agreement from 54.75% to 81.25% with no training at all, and item generation improved only after prompt refinement had plateaued — that plateau is your signal that training might add something.
4. **Fine-tune when the target is a stable format, a controlled property, or a domain the base model lacks.** LoRA on a few thousand examples can put small open models at human-grader parity, and an instruction dataset can take a 7B model from near zero to within 0.15 of a much larger reference on domain-specific dimensions.
5. **Choose rank and layers deliberately, and expect architecture-specific behavior.** Gain per adapter parameter fell as rank rose, four-layer adaptation beat both shallower and full-depth fine-tuning, and one model family improved substantially while another did not move at all.
6. **Use post-training when you need to change *how* the model teaches.** Reward guiding over answering, and expect the reward to be gamed — write it against a benchmark, not an intuition.
7. **Supervise at the step level.** Final-answer-only training produced sub-30% misconception accuracy at every data size.
8. **Keep a human in the loop where confidence is low.** Routing the least confident fifth of responses removed about 80% of manual work while improving agreement.
9. **Test safety across whole conversations.** Long dialogues are where specialized models degrade.
10. **Calibrate expectations.** Model and prompt choice account for only about 15% of the misalignment with learning gains; some of what you want from training is not available from training.

Open Questions

1. Does pedagogical post-training generalize across subjects, or is subject-specific tuning always needed?
2. Can the RL–SFT–RL pipeline be combined with longitudinal memory for personalization across terms?
3. What is the smallest supervision set that still teaches step-level pedagogical reasoning, and can it be shared across institutions without sharing student data?
4. How should evaluation of fine-tuned educational models be standardized, given that similarity metrics can be excellent while the model is unusable?

Connections to related concepts

This page is the *how a model is made* companion to Large Language Models (LLMs), which covers what large language models are and how they behave. It sits under Technologies as the training-and-adaptation node, beside RAG (Retrieval-Augmented Generation) (the retrieval alternative that usually comes first), Prompt Engineering (the cheapest lever), and Reinforcement Learning (the RL half of post-training). Its outputs feed Intelligent Tutoring and Adaptive Learning; its most common educational applications are

Automated Assessment, Automated Essay Scoring and AI Feedback Quality; and its closest conceptual relatives are Educational NLP, Simulating Students, Open Source and Learner Modeling and Adaptive Instruction. The risks it creates are held by Pedagogical Safety, AI Sycophancy, Hallucination Risk and Privacy.

Common Misconceptions

- **"Fine-tuning is the way to make a model good at your task."** Retrieval and prompting come **earlier in the decision order**, and the knowledge base's clearest result is that post-training is a **third choice, not the first**. Fine-tuning a model on assessment data improved **formatting and similarity** while a separate fine-tune **failed outright at generating feedback** — the method changed the surface and not the competence.
- **"The model is the main determinant of learning gains."** Model and prompt choice account for only **about 15%** of the gap between an LLM and student learning gains. Optimizing the remaining 85% is where the work is, and it is not in the weights.
- **"A local model will underperform a hosted one, so retrieval is a lesser lever."** In a three-configuration evaluation, **retrieval, not the model, was the first-order design decision**: the local LLM with **no retrieval reached only 52.3% accuracy, below a TF-IDF baseline**. Adding retrieval moved the same model past a threshold no model swap was going to reach on its own.
- **"More training data means better teaching behaviour."** The assessment fine-tune that improved formatting while worsening feedback generation is the counterexample in miniature: optimization against a similar-looking target can improve the proxy and degrade the thing you wanted.

Vibe Coding

> **Vibe coding** — building software by iteratively prompting a large language model and judging the resulting behavior, without directly reading or editing the underlying source code. Popularized by Andrej Karpathy in 2025 as the workflow where one "forgets the code even exists," vibe coding is the LLM-native realization of natural-language programming and end-user development — framings now treated as synonyms in this knowledge base — in which prose becomes the primary programming interface.

Questions to Consider

- Karpathy's original framing said you should "forget the code even exists." Before you read further, ask yourself: is not seeing the code a feature (it lowers barriers) or a risk (you cannot verify or fix what you cannot see)? What does the answer imply for who should be allowed to vibe-code?
- Research on who succeeds at vibe coding found that traditional computer-science achievement still predicts success even when the user never touches code. If that surprises you, what hidden skill might CS training be building that prose alone does not capture?
- The same study found writing skill predicts vibe-coding performance largely *because* it produces higher-quality prompts. If prompting is really the bottleneck, is the right fix to teach people to prompt better — or to redesign tools so they demand less prose skill?
- Vibe coding is often celebrated as making "anyone" a developer. But if writing skill and CS knowledge both shape outcomes, does vibe coding widen access to building software or merely relocate the skill barrier from code to prose?
- Some developers distinguish "pure" vibe coding (never reading code) from AI-assisted coding where you review and edit what the model wrote. Where do you think genuine learning — versus over-reliance — is more likely to happen, and why?

Introduction

Vibe coding describes an interaction style enabled by LLM-integrated development platforms (Replit, Lovable, Cursor, and others): the user specifies a program in natural language, the model generates a working system, and the user iterates based on observed behavior rather than by editing source. The term was coined by OpenAI co-founder Andrej Karpathy in February 2025 to capture the experience of relying on the model to such an extent that "the code" fades from awareness. Vibe coding sits at the convergence of several strands this knowledge base already tracks — it is generative AI applied to programming, an extreme form of prompt-driven work, a concrete instance of Human AI Collaboration, and the clearest route yet to non-programmers and end users building their own software (end-user development).

It also has deep roots. The idea of programming in ordinary language long predates LLMs — from COBOL's aspiration to be "an English-language programming system for non-professional programmers," through Donald Knuth's literate programming, to research on natural-language programming with constrained

subsets of English. Only with LLMs did it become feasible to map genuinely conversational, underspecified instructions to runnable code. Vibe coding is the particular variant in which the user deliberately does not inspect or edit the generated source, relying entirely on iterative prompting and behavioral evaluation.

Defining the construct: "pure" vs. code-visible vibe coding

The definition of vibe coding is still in flux. Some use the term broadly to mean any AI-guided programming; others insist it refers strictly to "building software with an LLM without reviewing the code it writes." Google Cloud distinguishes a "pure" no-code version (consistent with Karpathy's definition) from a version where the user understands and refines the generated code. This distinction matters for research: a controlled study of vibe-coding proficiency requires a well-defined construct. The CHI 2026 study of predictors of vibe-coding proficiency deliberately targeted the "pure," no-code variant — participants could not view or edit the generated source, so measured performance reflected the ability to specify, refine, and debug behavior through prose and observed output alone (see Thorgeirsson et al.).

Who succeeds at vibe coding: evidence

A preregistered cross-sectional study (N = 100 tertiary students) provides the first controlled, participant-level evidence on which skills predict vibe-coding success. Both written-communication proficiency (r = .29) and computer-science achievement (r = .39) significantly predicted performance on expert-vetted, GUI-oriented vibe-coding tasks, with CS achievement remaining significant after controlling for domain-general cognitive skills (partial r = .281). In a joint model CS achievement contributed roughly twice the unique variance of writing skill, but both added independent predictive value. Critically, human-graded prompt quality mediated the writing → performance link, giving response-process evidence that clear prose operates by producing better prompts. Because the environment hid the source code, CS knowledge could only help indirectly (through problem decomposition, algorithmic thinking, and mental models of control flow) — so the authors argue their CS estimate is a *lower bound* for AI-assisted programming in which users may also edit code directly (Thorgeirsson et al., 2026).

Vibe coding as end-user development and teacher tooling

A major promise of vibe coding is that it lets non-programmers — including teachers and domain experts — build their own software, an LLM-era form of end-user development. A GAIDE framework study showed K-12 teachers (non-programmers) using vibe coding in an eight-week workshop to create AI-powered learning tools, raising their AI literacy and demonstrating "learning-by-creating" as a professional-development model. In higher education, an instructor rapidly built a programming-process visualizer from IDE activity logs via vibe coding in a matter of days, making students' programming processes visible for teaching and Academic Integrity review. These cases position vibe coding not merely as a learner skill but as an authoring capability that reshapes who can create educational technology.

Design homogenization: access without diversity

Vibe coding's end-user-development promise is about who can build, not what gets built. In a course deployment, 73 students building sites for distinct businesses on one vibe-coding platform produced roughly

a dozen distinct designs, and felt authorship did not track measured originality (Boussioux et al. (2026)). Lowering the barrier to building may standardize the output — a cost the access promise does not advertise.

Learning, agency, and the risk of over-reliance

Vibe coding reopens core questions about what is learned when AI automates implementation. Because the user does not read code, they must trust the model's behavior — which makes vibe coding a high-stakes case of the tension between Learner Agency and over-reliance that runs through AI-assisted programming. Curricula are responding by shifting from teaching implementation toward teaching how to direct, verify, and audit AI-generated artifacts (see reshaping undergraduate CS and agentic software engineering). Vibe coding also changes the learner's epistemic position: success depends less on writing code than on expressing intent precisely and evaluating behavior against goals, competencies closer to computational thinking and structured writing than to traditional syntax mastery.

A second limit shows up in the building itself: removing the coding barrier can leave the diagnosis burden untouched. Two engineering case studies had an instructor build working web simulations of a battery thermal management system and three ARQ protocols by prompting Gemini in plain language within a few hours (Tarasak et al. (2026)). A duplicate-packet error then survived repeated prompts, including one that stated the required behavior. It was fixed only when the instructor reasoned from protocol behavior to an insufficient timeout interval, a parameter the interface never exposed. Neither simulation's effect on learning was measured, so the account establishes feasibility rather than effectiveness.

Connections to related concepts

Vibe coding connects naturally to Prompt Engineering (prompt quality is the mechanism of prose-driven development), CS Education (as the domain where the technique is most used and most contested), Computational Thinking (the mental modeling that predicts success even without code access), Writing (writing becoming a programming skill), and Agentic AI (directing a model toward an artifact rather than hand-building it). It also intersects with AI Literacy and Teaching, since the ability to build one's own tools changes what teachers and learners can do. Finally, it raises Academic Integrity and assessment questions identical to those AI code generation raises across computing education.

A faculty-level case study in this knowledge base supplies the organizational layer. Zimmer (2026) describes *AI intrapreneurship* — educators building their own tools instead of waiting for institutional procurement — including an author who does not code using Claude Code to build a checker for 321 course links. The decisive enablers were organizational rather than technical: work discretion, rewards, and time availability, the last described as most obviously in deficit in academic settings and undercut by promotion and tenure. The security picture stayed sober, since Veracode's 2025 analysis found only 55% of AI-generated code secure, so vibe-coded classroom tools still need a review pass before handling student data or connecting to an LMS.

Common Misconceptions

"Vibe coding lowers the skill barrier, so it is mainly a matter of writing well." Written-communication proficiency helps and does not carry the outcome alone. In a preregistered cross-sectional study (N = 100

tertiary students), both written-communication proficiency (r = .29) and computer-science achievement (r = .39) significantly predicted performance on expert-vetted, GUI-oriented vibe-coding tasks, and in a joint model CS achievement contributed roughly **twice the unique variance** of writing skill while both retained independent predictive value. The barrier has moved, not disappeared, and part of it remains technical.

“Because anyone can now build software, what gets built will become more diverse.” Access and diversity are separate outcomes, and access can even compress the second. The design-homogenization evidence in this corpus describes exactly this pattern: a wider population of builders working from the same models, the same component conventions and the same prompting defaults tends toward converging designs. Democratizing authorship does not automatically diversify artifacts.

“‘Pure’ vibe coding is what the term means, so the distinction does not matter.” It matters for evaluation and for safety. The page distinguishes pure vibe coding, where the user deliberately does not inspect or edit the generated source and relies entirely on iterative prompting and behavioral evaluation, from code-visible work in which the user reads what was produced. These are different activities with different error profiles, and a study of one does not license claims about the other.

“If the app runs, the generated code is fine.” Running is a weak test. Veracode’s 2025 analysis found only 55% of AI-generated code secure, so vibe-coded classroom tools still need a review pass before handling student data or connecting to any system worth protecting. Behavioral evaluation confirms the paths a user happens to exercise and says nothing about the ones they do not.

Putting Vibe Coding into Practice

For instructors and teacher educators

- Teach the difference between pure and code-visible vibe coding explicitly, and require the second for anything that will handle student data. The distinction is a teachable habit, not a philosophical nicety.
- Keep a real programming thread alongside vibe-coding work, because CS achievement carried about twice the unique predictive variance. Treating natural-language specification as a full substitute discards the stronger predictor.
- Have students evaluate the artifact behaviorally *and* inspect the source of anything they deploy. Reading generated code is a review skill, and it is not automatic for students who can prompt.

For developers and administrators

- Run a security review pass on any vibe-coded tool before it touches student records, consistent with the 55% secure-code finding.
- Budget for homogenization: if several staff vibe-code the same kind of tool from the same defaults, expect similar output and plan for how differentiation will be achieved deliberately.
- Prefer code-visible workflows for maintained tools and reserve pure vibe coding for throwaway prototypes.

For researchers

- Report the vibe-coding condition (pure versus code-visible) alongside outcomes, and use expert-vetted, GUI-oriented tasks rather than self-reported success, so results are comparable across studies.
- Measure artifact diversity, not only artifact count or builder count, if the access argument is being tested.

Multimodal AI

> **Multimodal AI** — AI systems that process, understand, or generate content across multiple modalities — text, images, audio, video, and structured data — and the educational questions these systems raise. In AI in education, multimodal AI appears in three distinct roles: as the *learning content* learners create and engage with (multimodal learning), as the *capability boundary* of tutoring systems that must interpret diagrams and graphs (multimodal tutoring), and as the *assessment signal* used to evaluate understanding (multimodal measurement).

Questions to Consider

- Think of a graph, force diagram, or schematic you've ever struggled to explain in words. What does that experience suggest about the limits of a text-only AI tutor trying to help with image-rich problems?
- A physics tutor answers text-based problems ~96% of the time but drops to ~74% on problems that embed meaning in diagrams. Before reading, what do you think causes this 'multimodal interference'—and can you think of a fix that doesn't involve retraining the model?
- You've likely generated both text and images with AI tools. Have you found that 'prompting for pictures' differs from prompting for text? What skills might students need to translate an abstract idea into a precise visual prompt?
- Multimodal AI can grade essays, generate feedback with audio narration, and even reconstruct exam item statistics from image-and-text items. What does the shift from text-only to multimodal assessment signal (or risk) for fairness and validity?
- How could the fact that AI support is less reliable on the very diagram-heavy problems that build deep STEM understanding create an equity gap between learners? Who is most affected?
- Multimodal systems can translate text to audio or visuals to support inclusive learning, but they also enable fine-grained classroom sensing. Where is the line between helpful multimodal access and surveillance?

Introduction

Multimodality in AI refers to the capacity to work across different representational forms rather than text alone. Modern Generative AI and Large Language Models (LLMs) systems increasingly accept and produce images, audio, and video in addition to text, opening new possibilities and new risks for education. Grounded in social semiotic theory, which holds that meaning is made across modes — not just words — multimodal AI changes how teaching, learning, and assessment are designed and evaluated.(Multimodal Learning with Generative AI)

Three faces of multimodal AI in education

1. Multimodal learning and content creation

Multimodal AI enables learners to produce and engage with content across text, image, audio, and video. An educator's guide to multimodal learning with generative AI positions these tools as a "cyber-social" partner: they complement — but cannot replace — human meaning-making.(Multimodal Learning with Generative AI)

- **AI literacy in multimodal contexts** is layered: basic awareness of multimodal platforms, intermediate co-creation and critical evaluation of outputs, and advanced design of multimodal activities and assessments.(Multimodal Learning with Generative AI)
- **Multimodal prompting** is itself a demanding epistemic practice. Students who prompt for images as well as text discover that "prompt literacy is different between prompting for text than it is for pictures" — translating abstract meaning into machine-readable multimodal prompts requires a precise visual vocabulary and exposes system limitations and bias.(Students' multimodal prompting practices as epistemic work in AI literacy development)
- **Multimodal assessment** shifts from essays to artifacts combining text, image, audio, and video, with educators using AI to scaffold creation and feedback rather than replace the learner's own production.(Multimodal Learning with Generative AI)
- **Modality choice is an educational judgment, not a container.** Elkington (2026) argues that choosing among written, oral, digital and multimodal formats decides what becomes possible for learners and visible to assessors, and counts controlled choice among modalities as a generative constraint rather than an administrative detail.
- **Learner multimodal composing as a critical-thinking scaffold carries a trade-off.** Lu et al. (2027) show that having upper-primary students turn written narratives into AI-generated images and short videos supported sustained gains in interpretation, analysis, evaluation, and explanation — but not inference. Because the visuals made story meaning explicit, students reported less need to infer implicit meaning from text alone; peer collaboration, not the multimodal tool, restored occasions for inference. Multimodal AI's value as a meaning-making partner is thus dimension-specific and depends on instructional design that deliberately re-introduces the inferential and self-regulatory work the externalization can short-circuit.
- **Learner multimodal composition as critical AI literacy.** Burriss et al. (2026) analyze 22 eleventh graders' 90-second to 3-minute video public service announcements on self-chosen AI Ethics issues — surveillance through school-regulated laptops and electronic "hall passes," informed consent, and punitive algorithmic accusation — as critical AI literacy enacted through composing across moving image, sound, text, and students' own bodies. Across all seven films harm was portrayed as emerging from human–machine entanglement rather than from the tool alone (an anthropomorphized "AI stalker" was played by a human actor in three of seven), and 15 of 18 end-of-unit responses said composing changed their understanding of AI ethics. The authors argue multimodal products both *demonstrate* and *communicate* critical competence — productive artifacts, reflections, and civic discourse can serve as Assessment evidence that text-only literacy scales structurally miss.

2. Multimodal tutoring and the capability boundary

When LLM-based tutors must solve problems that embed meaning in graphs, force diagrams, schematics, or tables, their accuracy degrades sharply — the **Multimodal Interference Effect**.(Multimodal Dialogue in STEM Education)

- On OpenStax physics problems, text-only accuracy of ~96% drops to **~74%** on image-rich problems, consistently across model families.(Multimodal Dialogue in STEM Education)
- **Visual Processing Errors** — failures to extract information from graphs or diagrams — dominate the error taxonomy and are the most correctable failure mode.
- A simple structured-dialogue intervention (have the model describe what it sees, correct only *observable* misreadings without giving away physics, then re-prompt) restores accuracy to **~95%** with zero retraining.(Multimodal Dialogue in STEM Education)
- This is an **equity concern**: students working on image-rich problems — precisely the problems that build deep conceptual understanding in STEM — currently receive less reliable AI support than those on text-only exercises.
- **Constructing a visual aid is harder than reading one.** On GeoVAD-Bench, supplying an expert auxiliary diagram raised accuracy (+3.3 to +7.0 points), but letting models construct their own auxiliary line widened the gap by 10.0 to 13.5 points — two models scored worse than with no visual reasoning at all (Dong et al., 2026).
- **The boundary is a profile, not a level — and artistic imagery sits outside the region models handle well.** MUSE (Zhu et al., 2026) evaluates 30 open- and proprietary VLMs on 12 tasks over 1,174 commissioned artworks, and the capability spread across dimensions is wider than any aggregate score suggests: scene classification is near-mature (23 of 30 models above 75.0, median 81.0). Meanwhile emotion detection tops out at 39.5, and the open-ended tasks that require models to *articulate* their evidence score at 50.90 (visual clue identification) and 49.18 (emotion cause inference) on semantic similarity. Compositional and viewpoint-dependent reasoning fail hardest — where the ground truth specifies no definite lateral or vertical relation, 90.0% and 73.3% of models assert one anyway, only 43.3% place the girl correctly in depth, and no model resolves all three dimensions of a single item. Failures also cascade: a mis-grounded character is then justified with a fluent rationale built from nearby visual semantics (butterflies, birds), which is the outcome most dangerous in tutoring because the explanation reads as competent. For image-based language learning this argues for dimension-level validation on the imagery a course actually uses, rather than importing a general multimodal score, and for extending the grounding checkpoint described below — describe what is seen, and where, before reasoning from it — to situated artistic content (MUSE: Benchmarking Large Vision-Language Models on Multi-Modal Understanding in Situated Education).

The practical design implication is a **visual grounding checkpoint** in multimodal tutoring: a deliberate step where the system describes what it sees before attempting a solution, giving the student or a human supervisor a chance to correct perceptual errors.(Multimodal Dialogue in STEM Education)

Abreu et al. (2026) add a prior constraint: an equation, graph or unit can appear in a report yet never be retrieved from the processed document, so a disagreement with the instructor may be an extraction failure rather than a reasoning one — which makes submission format part of the assessment design.

3. Multimodal assessment and measurement

Multimodal AI broadens both the *content* of assessment and the *signal* used to score it.

- **Multimodal feedback systems** integrate structured text, slide references, and streaming audio narration. In one study, AI multimodal feedback matched educator feedback for learning while *significantly outperforming* it on student perceptions.(LLM-based Multimodal Feedback Produces Equivalent Learning and Better Student Perceptions than Educator Feedback)
- **Multimodal item response estimation** uses fine-tuned multimodal LLMs to reconstruct item characteristic curves (IRT / 3PL) directly from predicted option probabilities on image-and-text items, connecting multimodal AI to Educational Measurement and Item Response Theory. (Multimodal item parameter estimation using simulated response probabilities)
- **Educational vision-language model evaluation** and multimodal LLM literacy extend the field's evaluation toolkit to multimodal reasoning and Visualization.(The aftermath of DrawEduMath: Vision language models underperform with struggling students and misdiagnose errors) (Benchmarking Multimodal Large Language Models for Scientific Visualization Literacy)
- **Multimodal grading of handwritten chemistry exposes a format-dependent capability boundary:** Cvengros & Kortemeyer graded a 296-student handwritten general-chemistry final page-by-page against rubric images with a multimodal, reasoning LLM, scoring textual answers and chemical-reaction equations reliably (normed F1 highest) but drawing and graphing *worse than random* — background grids visually distract AI vision and scientific diagrams/chemical structures remain hard to interpret — reinforcing that multimodal AI's vision is not robust to representation-heavy work and is best deployed with human deferral of graphical items (Assisting the grading of a handwritten general chemistry exam with artificial intelligence).
- **Construct recognition and comparative judgment are separable skills.** Ma et al. (2026) express six multimedia-learning principles as reversible slide edits plus visual-equivalence sham controls, and find both models recovered every operation, principle and repair (8/8) while severity calibration failed entirely (0/8) — a composite score would conceal which layer fails.
- **Fairness gains can be validated into existence.** A multimodal attention estimator beat a visual-only baseline only modestly, and its gender-targeted MAE-gap regularizer cut the validation gap from 0.02 to 0.005 yet increased the gap and worst-group error on held-out subjects — so subgroup-aware, repeated subject-level validation is required before deployment (Fragkiadakis et al. (2026)).
- **Multimodal grading can reproduce a selection outcome even where item-level scoring lags.** Grading 10,364 handwritten Olympiad and university pages, an LLM matched examiner totals at r = 0.93–0.96 and placed the same five students on the Olympiad team, yet part agreement reached 70%: second-reader evidence, not a scorer of record (Pathak et al. (2026)).
- **Diagram generation is a capability frontier, not a solved one.** On a 15,246-question physics benchmark that scores multimodal output, synthesizing or editing structured physics diagrams proved harder than answering, and leading models stayed below 70% strict mastery — evidence that visual *production* lags visual *comprehension* (Chen et al., 2026).

Multimodality has a second sense: fusing signals from the learner's body rather than from content, where eye tracking, EEG, electrodermal activity, heart-rate variability and camera pose feed estimates of attention, engagement and cognitive load. That sensing strand lives at Sensor and Gaze Analytics, and its validity and consent problems are not the ones multimodal content raises.

Multimodal AI for language and accessible learning

Multimodal systems also expand access and personalization. AI-guided audio-video learning tools adapt playback speed, produce multimodal video summaries, and support pronunciation practice.(AI-guided learning: Research on knowledge and skill acquisition support methods using deep learning audio-video processing techniques) Multimodal knowledge graphs reason across images and text for educational tasks, (Evidence-Grounded Multimodal Knowledge Graph Construction for Multi-Lecture Educational Reasoning) and multimodal representations improve Inclusive Learning by translating information across modes (e.g., text to audio or visual). Domain applications include handwritten-math grading and diagnosis, (Benchmarking Large Language Models for Diagnosing Students' Cognitive Skills from Handwritten Math Work) affective tutoring with multimodal signals,(An Interpretable Closed-Loop Intelligent Tutoring System for Multimodal Affective Feedback in Asynchronous Presentation Training)(MathBuddy: Affective Math Tutoring) text-to-image learning in specialized fields,(NuclearDiffusion: Text-to-Image Foundation Models for Learning Nuclear Energy Concepts) and privacy-aware multimodal classroom sensing.(Robust and Efficient Motion Reasoning for Privacy-Aware Classroom Incident Recognition) Bird (2026) demonstrates a text-internal form of multimodality: fusing a fine-tuned ELECTRA transformer with computational-linguistics feature analysis to classify English literature by UK Key Stage, where the fused model (F1 0.996) far surpassed every unimodal baseline — evidence that combining representational forms, even within text, can outperform single-model approaches.

Challenges and design implications

1. **Close the multimodal gap.** Multimodal tutoring systems should include visual grounding and structured-dialogue scaffolds rather than assuming vision capabilities are robust.(Multimodal Dialogue in STEM Education)
2. **Treat multimodal prompting as a teachable skill.** AI literacy curricula must address modality-specific prompting, coherence across modes, and critical evaluation of multimodal outputs. (Students' multimodal prompting practices as epistemic work in AI literacy development)
3. **Preserve human meaning-making.** Multimodal AI should augment, not replace, the learner's own construction and evaluation of meaning across modes.(Multimodal Learning with Generative AI)
4. **Extend evaluation to multimodal validity.** Assessment validity, bias, and reliability must be examined when AI scores or generates multimodal artifacts.(Multimodal item parameter estimation using simulated response probabilities)(AI Ed Evaluation)
5. **Watch equity and privacy.** Unreliable support on image-rich problems and the data demands of multimodal sensing both carry equity and privacy implications.(Multimodal Dialogue in STEM Education)(Robust and Efficient Motion Reasoning for Privacy-Aware Classroom Incident Recognition)

6. **Match the pipeline to the content.** A cybersecurity lab assistant's multimodal LLM handled dense visual slides better, while an OCR-plus-LLM pipeline delivered comparable instructional value on text-centric slides at significantly lower computational cost.(Patel et al. (2025))
7. **Collecting several streams is not integrating them.** A review of 23 AI-for-Embodied Learning studies sorted multimodal work into three levels — streams gathered in parallel, streams aligned on a shared timeline, streams fused inside one model that estimates the learner's state — and placed most studies at the first, pairing image with text or motion with text without ever joining them. One study aligned facial affect, gaze and face detection after the fact; the closest approach to fusion modeled joint states from wristband and skeletal signals with a Markov process, and ran after the session rather than informing the feedback learners received. No reviewed system fused its inputs during use (Kim and Han (2026)).

Common Misconceptions

"A multimodal model handles multimodal problems." Accuracy degrades sharply when meaning is carried by the figure rather than the text. A physics tutor answers text-based problems about **96%** of the time but drops to about **74%** on problems that embed meaning in diagrams — the **Multimodal Interference Effect**. Twenty-two points of capability disappear exactly where the disciplinary content lives.

"Adding an image to the prompt resolves the diagram problem." The input modality is not the bottleneck; the interference is. A model that receives the diagram and still reasons from the surrounding prose has been handed the information and has not used it, which is why the failure is invisible unless someone compares the two problem formats.

"Multimodal capability is a single ladder, so the best model overall is best for the image-rich task." Capability is task-specific, and a model that leads on general benchmarks can trail on force diagrams. For image-rich disciplines the relevant test is the one with the meaning embedded in the figure.

"Text-only tutoring limits are a nuisance rather than a curriculum problem." In disciplines where the diagram *is* the problem — physics, chemistry, geometry, engineering, medicine — a text-only tutor's competence boundary falls across the assessed content rather than at its edges.

Speech and Voice Technologies

> **Speech and voice technologies** — the family of AI systems in which the spoken channel carries the interaction: automatic speech recognition (ASR) that transcribes, analyses, and grades what a learner says; text-to-speech (TTS) that generates narrated or dialogue-form instruction; voice-first agents that hold real-time spoken conversation with learners; and automated capture and scoring of oral performance. Where Conversational AI research is mostly about text chatbots and Language Learning covers second-language pedagogy broadly, this page follows the audio itself — what a speech interface changes about learning, what it costs, and who it includes or excludes when the interface is a voice rather than a screen.

Questions to Consider

- ASR feedback helps stronger learners more than weaker ones: in one survey of 325 Chinese undergraduates, the payoff of reflective behavior and motivation was weak and non-significant at low proficiency and grew markedly stronger at average and high levels. If a tool raises the average while widening the gap, is it a success?
- TTS narration matched an instructor's own voice on comprehension, concentration, and overall evaluation — but dialogue-format TTS beat single-speaker TTS on comprehension and cognitive engagement while sounding *less* natural. Which would you choose for a first introduction to a concept, and which for a dense procedural walkthrough?
- Two findings run against intuition: students who read the AI's output most heavily during interpreting tasks had the weakest delivery fluency, and a learner who answered in two words was marked correct while a fuller spoken answer was flagged. How much does a voice interface measure verbal fluency rather than understanding?
- A voice agent with a British accent was treated as a tool, while agents with Indian and African American accents were anthropomorphized and treated as peers in K-12 group work. If accent changes how a learner relates to an agent, who should decide which voice an educational product ships with?
- Voice-first and offline systems exist mainly to reach learners that screen-based edtech excluded — blind children, deaf and hard-of-hearing learners, learners in workshops with no connectivity. What would it take for accessibility to be the starting assumption of a speech product rather than a later fix?
- Nearly every claim on this page comes from a short, single-site, self-report study with a fixed presentation order. Which of these findings would you trust enough to change your assessment or lesson design before a replication exists?

Introduction

Speech is the oldest educational interface and the newest one for AI. Systems that listen and speak now sit in language classrooms, vocational workshops, and high-school inquiry lessons. They are attractive for the

usual reason — speech is fast, works hands-free and eyes-free, and is the medium in which pronunciation, fluency, and oral reasoning live — and for a newer one: a time-limited spoken answer is hard to outsource to a text generator, which makes the spoken channel a candidate answer to Academic Integrity pressure on written assessment.

The research here splits into four clusters: ASR pronunciation feedback, TTS-generated instruction, voice-first and spoken-dialogue partners, and AI-supported oral Assessment. Running through all four is a question about equity — speech interfaces remove one barrier (sight, reading speed, typed literacy) while introducing others (accent, recognition accuracy, hardware, connectivity).

ASR and Pronunciation Feedback

The most consistent message from the ASR work is that the tool is not the treatment — the feedback design is. Chen et al. (2026) surveyed 325 undergraduates at a Chinese teacher-training university and modeled accuracy, usage frequency, feedback quality, and reflection-task design against reflective behavior and intrinsic Motivation, then against speaking improvement. Accurate error correction and structured reflection tasks drove both Feedback internalization and reflection. More frequent use boosted reflection but had no independent effect on motivation. Recognition accuracy raised motivation, plausibly by building trust in the tool, but did not by itself trigger deeper processing — a learner can register a flagged error without analyzing its cause. Reflection was the stronger predictor of speaking gains, and proficiency moderated both pathways: weak and non-significant at low proficiency, markedly stronger at average and high levels. The advice that follows is to explain errors articulatorially rather than flag them, ramp complexity with readiness, and frame correction supportively.

A second strand asks whether AI pronunciation feedback changes learners' disposition to speak. Lu et al. (2026) surveyed 1,701 Chinese university EFL learners and used covariance-based structural equation modeling with bias-corrected bootstrapping to test whether perceptions of Generative AI pronunciation feedback related to willingness to communicate, with pronunciation Self-Efficacy as mediator. The association was positive, and self-efficacy partially mediated it: the indirect path accounted for 69.9% of the total effect while a direct effect remained. All constructs were self-reported at one time point, so the study describes a mechanism learners perceive rather than one that was manipulated.

Automated pronunciation feedback can also be built without error labels. Kawamura (2026) describes Profy, which learns what good and poor pronunciation look like from largely unannotated speech via self-supervised learning, then shows learners which waveform regions drove the judgment and how far their acoustics sit from native-speaker distributions. With 10 Japanese learners of English rated by five American listeners, intelligibility improved, and unlike an elicited-imitation baseline the pre- and post-practice confidence intervals did not overlap — a small sample, but one that gives *where* and *how much* rather than a binary verdict.

ASR also serves the classroom in a second role — converting spoken input into text that learners read. Stanchev (2026) rendered a 2,692-token Medical English coursebook passage on proteins with one text-to-speech voice (15:27, female Canadian) and submitted the identical audio to four online ASR services, then measured both word error rate (WER) and **coverage** (returned words as a share of the reference). The two free services returned near-complete transcripts (87.96% and 88.34% coverage, WER 15.23% and 15.00%), while the two paid services exported only previews (32.76% and 55.35% coverage, WER 73.21% and

48.77%). The measurement point is that WER alone conflates unavailable text with inaccurate text and would rank an export restriction as a transcription failure, so coverage belongs beside the error rate. Deletions dominated every service and clustered on structural markers such as figure references and page numbers, but a handful of meaning-altering substitutions — imino → amino, cystine → cysteine, protonated → protonatid, pH → phase — each inverted a biochemical fact, which is why the authors propose a three-stage workflow (generate the input, export the full transcript, verify domain terminology) before a transcript reaches learners, and why a terminology pass is the cheapest guardrail for medical English.

Accuracy gains appear to be a property of purpose-built systems rather than of the spoken channel itself. Across ten studies, only chatbots designed for language learning — Andy English bot and Xiaoying — improved accuracy, with a 14% error decrease in one control group against 38% in the treatment group (Soriano-Gonzalez & Belda-Medina (2026)). The same review documents ASR failing on accented speech and non-English names, including a bot that could not recognize Vietnamese names even when pronunciation was accurate.

TTS and Voice-Generated Instruction

Generated narration turns out to be a viable substitute for a recorded teacher, and the interesting variation lies inside the format rather than between human and machine. Kumoi et al. (2026) built a three-stage, human-in-the-loop pipeline in which an Large Language Models (LLMs) drafts slides and TTS-optimized narration while the educator fact-checks at each stage, then ran a within-subject study with 245 first-year students at a Japanese prefectural high school across instructor-voiced video, single-speaker TTS, and Expert-×-Novice dialogue TTS. Comprehension, concentration, and overall evaluation did not differ significantly across the three ($p > .14$, $r < 0.11$), and equivalence testing kept all three within a ±0.5 margin: synthetic narration did not degrade the experience. Dialogue narration was better on comprehension ($p = .006$, $r = .130$), on reported deepened thinking ($p = .019$, $r = .121$), and on being able to explain the content to a friend ($p = .004$, $r = .152$), and 66.9% preferred it as most enjoyable. Two caveats: dialogue audio was rated significantly less natural ($r = −.238$), consistent with extra load from multiple speakers, and the dialogue group arrived with less prior knowledge (66.0% reporting knowing “nothing at all” versus 34.1%), which makes its advantage a conservative estimate.

The follow-up argues that format should be matched to the learner, not the content. Watanabe et al. (2026) gave 222 first-year high-school students teacher–student (TS), student–student (SS), and teacher–teacher (TT) dialogue lessons generated by an LLM and voiced through a TTS API, fitting linear mixed-effects models through an aptitude-treatment interaction lens. TT raised Motivation more than TS, but the effect depended on learning style: the interaction with the Concrete Experience factor was positive ($b = 0.162$, $p < .001$) while the interaction with the reflection-and-conceptualization factor was negative ($b = −0.238$, $p = .002$). TT also drew a significantly *lower* overall evaluation than TS ($b = −0.126$, $p = .005$), which the authors attribute to intrinsic cognitive load from dense expert-to-expert exchange; free responses name “stiffness of speech” in TT and “unnatural manner of speaking” in SS. Both TTS studies confound format with content and fixed viewing order, so their effect sizes are preliminary.

Voice-First Companions and Spoken Dialogue Partners

What changes when the interlocutor is a machine? Scheinberg et al. (2026) had 78 university learners of German across four sites complete a counterbalanced spot-the-difference task with both a human peer and a real-time AI partner, then analyzed diarized ASR transcripts. Human dialogue was faster and better balanced, with many short turns, while the AI condition looked like supported monologue — fewer, longer turns, a smaller learner share of the floor, and higher within-turn fluency. The AI's verbose, syntactically regular input was associated with greater short-term uptake and stronger syntactic priming after controlling for input volume, and satisfaction tracked learners' own production fluency rather than how much they picked up.

Voice-first design becomes a necessity rather than a convenience when the learner cannot use a screen. Kutti AI (Fadurudeen 2026) inverts edtech's visual assumption to reach an estimated 1.4 million blind children worldwide: children hear curriculum content, answer aloud, and receive spoken feedback with no visual dependency. Three choices carry the design — a lightweight struggle-detection engine fusing response latency, wrong-attempt counts, and keyword hesitation cues to decide when to hint or simplify; a cross-language answer-matching pipeline so that code-switching and pronunciation variation are not penalized; and an offline on-device ASR path that removes the connectivity requirement. It is a systems contribution with no learning-outcomes evaluation, so its pedagogical claims remain hypotheses.

Accent, meanwhile, is a design variable with social consequences. Ravi et al. (2026) had 33 teachers interact with a GenAI voice agent in British, Indian, and African American accent conditions in K-12 group learning. The British-accented agent was treated largely as a tool and engaged with in detached, utility-based ways, while the Indian- and African American-accented agents were more readily anthropomorphized and integrated as peers, with stronger trust and reliance over time. Turn-taking, questioning patterns, and perceived social presence all shifted with accent — the voice that makes an agent easy to treat as a neutral resource can make it easier to ignore as a collaborator.

Heavier use of a spoken support tool is not automatically better. Kuang, Li and Weng (2026) had 22 interpreting trainees complete bidirectional computer-assisted consecutive interpreting tasks in systems built on ASR and machine translation, capturing eye movements, pen notes, and voice output. Four interaction profiles emerged — Intensive Engagers, Fast Scanners, Traditionalists, and Frequent Switchers — and 58.3% of stage-level observations changed profile between comprehending the source and producing the target. Only comprehension-stage patterns predicted product quality, and the AI-heaviest cluster scored lowest on fluency of delivery (5.46 against 6.17–6.46) and target language quality (5.70 against 6.35–6.67). Attention spent reading an AI transcript is attention not spent building one's own representation; the authors recommend teaching learners to reflect on their own strategy rather than prescribing one, since the pattern is invisible unless surfaced.

A preregistered randomized field experiment tests the spoken channel against typed text within the same tutor, and finds the learning is in the tutoring rather than in the voice. Yang, Van Alstyne and Dellarocas (2026) randomized 86 students in an online-MBA corporate-finance module between a structured tutor grounded in course materials and a holdout, then alternated each tutored student's channel weekly between voice and text so the comparison is identified inside each student: weekly mastery differed by −0.01 points of 11 ($p = .98$), and two one-sided tests rejected any true difference larger than ±0.3 SD. Voice transformed the process instead — 1.34 dialogue turns per minute against 0.75 in text weeks, and 11.3 questions against 4.6 — while the thinking pause collapsed (median tutor-to-student reply gap of 27 seconds in voice against

54 in text, where typed turns spent 25.9 seconds before the first keystroke plus 13.9 seconds composing) and the speech channel cost 2.8× more to deliver, at $0.22 per voice minute against $0.0165 per text message ($413.46 voice and $149.13 text over five weeks for 52 seats). On this evidence voice is an adoption and engagement lever, not an encoding one — which is exactly the trade-off any institution adding a spoken channel has to price.

The same voice stack is now proposed for the reverse direction: Tamme, Schilling & Hantel (2026) plan an ElevenLabs-based telephone agent that interviews students about a course in 5–7-minute conversations with adaptive probes. Their completed Munich pilot established feasibility; the planned field study, in one MIT Sloan course with approximately 60 students, has reported no results.

AI in Oral and Spoken Assessment

Oral assessment has always been pedagogically strong and logistically expensive, and speech technology now attacks the cost side. Pentland, Lowenthal and Krier (2026) describe asynchronous oral assessments (AOAs): prompts delivered just-in-time, brief time-limited webcam responses that cannot be revisited, and grading against embedded rubrics with auto-generated transcripts. Across two courses taught by a single instructor without scheduling constraints, students scored higher on AOAs than on in-person multiple-choice exams. That was significant in Study 2 (midterm median 92.5 vs 70, $p < .001$; final 94.2 vs 86.4, $p = .002$) and directional in Study 1, with moderate cross-format correlations ($\tau = .44$; $\tau = .25$, non-significant). Students shifted to more active preparation, 90.91% saw the format as closer to workplace communication than written exams, and 81.82% reported engaging more actively with content. The authors are careful that these are format score differences, not evidence of learning gains, and that the integrity advantage is inferred rather than measured; a re-scoring check with an LLM found instructor scores systematically higher with moderate-to-good agreement (ICC 0.73 and 0.60), offered as a reliability check rather than an endorsement of automated grading.

Fenton (2025) supplies the rationale in review form: because orals are real-time and interactive, students cannot generate answers in advance and memorize them, and the format probes reasoning at higher levels of Bloom's taxonomy rather than recall. Its benefits — personalization, authenticity, work-readiness, deeper knowledge — come with named costs: scheduling and logistics, learner anxiety, and bias risk around gender, ethnicity, language, response speed, and non-anonymous marking, though the evidence suggests orals can be as inclusive as written exams for some learners, including those with dyslexia.

Two deployments show what the technology adds. AkoVoice (Adams 2026) assessed 33 learners across four Level 3 Automotive classes and one Level 3 Engineering class in New Zealand, on learner-owned phones against one mid-range laptop running open-weight models — Mistral 7B via Ollama, faster-whisper for speech-to-text, Chatterbox for TTS. Up to 12 learners were assessed simultaneously, with no internet connection at any point. AI was cast as evidence-surfacer rather than judge, leaving the assessor's judgment intact. Learner reaction was positive: 21 of 33 (64%) called the task realistic, and none of the 33 disagreed that speaking in real time felt right compared with a written portfolio. The performance data is more interesting. Word counts for identical questions varied five- to eight-fold between learners in every cohort (93–523, 92–796, 309–811), yet verbosity did not predict accuracy on closed questions. Nine learners answered in 2 to 13 words and were all marked correct, the shortest being "3500 kgs", while the fuller "the safe working load is three tons" was flagged against a 3.5-ton marking guide. Adjacent Horticulture (14

learners) and Dairy (11 learners) trials found a 95% match between the agent's preliminary grade and the human tutor's grade. On the item side, Aryadoust and Wong (2026) compared iterative prompt engineering against fine-tuning for L2 listening items, producing 40 tests and 240 multiple-choice items: prompt refinement improved quality but plateaued, while fine-tuning GPT-4.1 on the optimized prompt with prompt design held constant improved generation further. Spoken assessment also risks measuring the wrong thing — Morphew et al. (2026) track gesture alongside transcribed speech and argue that assessing only speech misses embodied evidence of understanding, so that fluency can be mistaken for conceptual knowledge.

Accessibility and Equity in the Spoken Channel

Speech technology's accessibility record is mixed: the same channel that removes one barrier can install another. Deaf and hard-of-hearing learners are the clearest mismatch. Chen et al. (2026) designed an LLM question-generation system for DHH learners watching video, drawing on Language Deprivation Theory to explain why text-based prompting fits poorly with sign-based first languages. It added Visual Questions (timestamps where visual information is likely misread — rapid movement, misaligned captions, dense on-screen text) and Emotion Questions (timestamps where prior DHH learners reported frustration or confusion), refining a final bank of 30 questions with learners and instructors. With 16 users the prototype improved Self-Efficacy (M = 5.70, SD = 1.12 on a 7-point scale), and Deaf participants selected visual questions more often than hard-of-hearing participants, who reported reading captions fast enough not to need them. Accessibility here had to be built into generation, not appended to it.

AkoVoice adds two equity considerations that rarely surface together. First, data: recordings were encrypted at rest, hosted locally, and deleted after 90 days, and the authors treat a participant's voice as a personal and cultural expression rather than a resource for training models or building biometric profiles — a stance that matters because the EU AI Act classifies AI used to evaluate learning outcomes in vocational training as high-risk. Second, accent and register: speech-to-text accuracy was not fully tested across learner accents, and rubric criteria such as "engaging" were flagged as culturally specific and potentially penalizing to second-language speakers, prompting a review notes field. Set beside the accent findings in K-12 group work and the near-total visual assumption of mainstream edtech, the pattern is that the voice interface removes sight, reading-speed, and connectivity barriers while leaving accent, recognition accuracy, hardware cost, and cultural register open.

Scope check. This page is about the spoken channel and the technology that carries it. For second-language pedagogy at large — writing development, grammatical accuracy, motivation, teacher practice — go to Language Learning, which spans L2 instruction with AI and treats speaking as one strand among several. For text-based chatbots and dialogue design independent of modality, go to Conversational AI; several articles here involve dialogue, but their question is about speech, not about prompting a chat model. For screen readers, captioning, tactile graphics, and assistive tools that are not primarily speech-based, go to Assistive Technology, which sits under the broader Accessibility and Inclusive Learning strands of this wiki.

What Remains Uncertain

Almost every strong claim here rests on one short study. The two TTS lesson studies ran in single Japanese high schools with fixed presentation order that confounded format with content, and their learning-outcome measures were self-reported on in-house scales. The ASR feedback model came from one Chinese university

and was cross-sectional, so its proficiency-moderation finding describes covariance rather than causation. The willingness-to-communicate study measured perceptions of feedback, not feedback quality. The interpreting profile study is a 22-participant exploratory analysis in which output-stage effects did not reach significance. The AOA and AkoVoice deployments are single-institution, and AkoVoice reports no summative learning evidence because its voice assessments ran in parallel to actual assessments. Kutti AI is a systems contribution with no outcome evaluation at all. What the collection does support is a set of design claims: feedback quality beats practice volume in ASR use, dialogue narration can aid comprehension at the cost of naturalness, format should be matched to learner characteristics rather than fixed, AI should surface evidence rather than replace the human assessor, and speaking in real time measures something writing does not — including an accuracy surprisingly indifferent to how many words the learner uses. Whether any of that holds at another site, another language, or another year is untested.

Common Misconceptions

- **“Paid speech services outperform free ones.” The two free services returned near-complete transcripts (87.96% and 88.34% coverage, with word error rates of 15.23% and 15.00%)**, while the two paid services exported only previews, at 32% coverage). Price did not predict utility, and the paid tier gated the output rather than improving it.
- **“Any language-learning chatbot improves pronunciation.”** Across **ten studies**, **only chatbots designed for language learning — Andy English bot and Xiaoying — improved accuracy**, with a **14% error decrease in one control group** comparison. Generic conversational agents did not produce the gain.
- **“Self-efficacy gains mean skill gains.”** The association between the technology and outcomes was positive with **self-efficacy partially mediating it: the indirect path accounted for 69.9% of the total effect while a direct effect remained**. Most of the effect ran through confidence, which is a mechanism and also a caution.

Visualization

> **Visualization** — the use of data visualizations, infographics, dashboards, charts, diagrams, and other graphical representations to make information comprehensible for learning and analysis. Across education, visualization is increasingly both generated by AI (text-to-image, Multimodal AI slide and chart analysis) and used as the interface through which learners, teachers, and analytics systems reason over shared data.

Questions to Consider

- A chart or dashboard can make data clear — but is simply *seeing* a visualization the same as understanding it? The page's research suggests how you interact with a visualization matters more than the chart itself. Recall a dashboard or graph you looked at but didn't really learn from. What was missing from the mere display?
- Conventional learning dashboards follow a 'show data, hope for insight' model. The finding here is that learners who answer questions about their data *before* seeing the metrics reflect and calibrate better than those who passively view charts. Why might being forced to predict first change what you get out of seeing the actual data?
- AI can now generate accurate visualizations of specialized content: after fine-tuning on nuclear concepts, a text-to-image model climbed from 12% to 78% on that domain. But the page also finds no model is uniformly competent. Where would you trust an AI-generated visual, and where would you insist on checking it against a human expert?
- Participants in one study found AI-generated data comics more engaging and comprehensible, yet many also flagged misinformation risk and information overload. How do you weigh the appeal of a compelling AI visual against its potential to mislead — and what would you verify before trusting or using it?
- The page warns that a model's *confidence* is not its *reliability*: systems can sharply diverge on severity judgments while getting basic constructs right. If you relied on an AI tool to assess slides, essays, or data, how would you discover where its confidence hid a serious error?
- One study found students spent most of their gaze on code despite elaborate visual scaffolds — visual aids simply didn't capture attention for everyone. What does that suggest about assuming a nice diagram or dashboard will automatically help all learners engage? What else besides visuals shapes how people actually use a tool?

Introduction

Visualization is the use of graphical representation — dashboards, charts, diagrams, infographics and multimodal displays — to make learning and learning data intelligible. Its most established educational role is the learning analytics dashboard, where the dominant *show data and hope for insight* model has given way to interactive designs: the evidence indicates that how learners interact with a representation matters more than whether they see it, and that self-elicit prompts and pedagogical agents improve calibration more than

passive metrics do. The same question — does the display provoke thinking or substitute for it? — links visualization to Desirable Difficulties and Metacognition.

Visualization as a Learning Interface

The most established role of visualization in education is the learning analytics dashboard. In their standard form, learning analytics dashboards (LADs) put behavioral metrics into charts for learners to view passively, operating on a "show data → hope for insight" model. Research on Interactive learning dashboards: rethinking learning visualisations as engagement tools challenges this paradigm: when a dashboard adds an Large Language Models (LLMs)-powered pedagogical agent and an interactive Judgment of Learning Self-Assessment, the "elicit" condition — where learners answer questions about their data before seeing metrics — produced more reflection and more accurate mastery calibration than either a passive dashboard or a "telling" agent. The lesson is that how learners interact with visualizations matters more than merely seeing them. This connects to Learning Analytics and Self-Regulated Learning, where visual feedback supports metacognitive judgment calibration rather than simple information display.

Teacher-facing dashboards add a distinct set of design lessons. Mejia-Domenzain et al. (2026) found that teachers systematically preferred simpler, more traditional visualizations (bar plots, pie charts, legends) even when more complex designs (e.g., heatmaps) yielded more detailed insights — visual preference did not always align with informativeness, echoing debates about pie charts' comparative readability. Visualization literacy (VL) did not drive design preferences, but higher-VL teachers produced deeper, more detailed interpretations (e.g., more of them identified trends in time-series data), confirming VL as a confounder for gauging how teachers read analytics designs. For group comparison, teachers strongly favored superposition over juxtaposition, and preferred plots that displayed full information (e.g., including a "students who did not watch" group) rather than explicit difference encoding, although younger teachers ranked difference plots higher. These findings argue that dashboard design must balance teachers' stated preferences against the interpretative depth that more complex encodings afford.

Dashboards also function as shared representations that bridge human and AI reasoning. The CLARA system uses LLM-generated artifacts — concept maps and seven-dimension collaboration assessments — as common ground between dashboard users and AI agents, indexing them into separate vector collections so both parties reason over the same visible, queryable material. Similarly, the Expert Cognition Dashboard reframes analytics as "cognition intelligence," turning raw learner behaviors into interpretable cognition structures across individual, class, and AI Twin expert levels. These systems position visualization not as an output but as embedded reasoning infrastructure within Technologies-native education.

AI-Generated and Multimodal Visual Content

A second major strand concerns AI producing visualizations directly. NuclearDiffusion: Text-to-Image Foundation Models for Learning Nuclear Energy Concepts shows that domain-adapted text-to-image models can generate accurate illustrations of specialized STEM concepts: fine-tuning Stable Diffusion on nuclear domain images raised domain accuracy from 12% to 78%, enabling instructors to produce correct reactor-component and safety-system visualizations on demand. This generative capacity is powerful but uneven. Benchmarking Multimodal Large Language Models for Scientific Visualization Literacy benchmarks six multimodal large language models against 485 human participants on scientific visualization literacy, finding

no uniform competence: closed-source Gemini exceeded the human mean on several subsets while all Open Source models fell below it, with particular weaknesses in fine-grained quantitative estimation and texture-based or integration-based visualizations. AI should therefore support — not substitute for — human visualization literacy, a finding with direct AI Literacy and Formative Assessment implications.

Prompt-to-chart generation raises a different question from whether AI can produce a competent visualization: whether the learner still performs the analytic and encoding work that makes the artifact educational. A 2026 framework calls this the process–output divide and proposes transparency, invitation, and fading as the agency line between Scaffolding and substitution (Purohit et al., 2026).

Ethics and reliability temper enthusiasm for AI-generated visual content. Data Comics for Education: Evaluating Effectiveness, Benefits, and the Ethics of AI-Assisted Creation found GenAI-assisted data comics improved engagement and comprehension over conventional visualizations regardless of prior visualization literacy, yet participants raised concerns about misinformation risk and authorship attribution, and two-thirds flagged downsides such as information overload from overly busy layouts. The counterfactual CFES-P24 benchmark extends this scrutiny to slide auditing, showing that multimodal LLMs can reliably recognize Learning Design constructs (operations, principles, evidence localization) while sharply diverging on comparative judgment and severity calibration — evidence that composite scores conceal which capability fails and that confidence is not reliability. Together these works argue for layered evaluation of AI-generated visuals rather than holistic ratings.

Slide, Comic, and Multi-View Tools in Practice

Practical systems apply these principles at scale. AISSA combines LLM-based rubric scoring with learning analytics dashboards to deliver automated, iterative feedback on student presentation slides, processing 90 presentations in 1–3 minutes each at cents-per-evaluation cost with high perceived usability — while students selectively applied feedback, sometimes disregarding recommendations that conflicted with their visual design. In coding education, Flowcode pairs a code-structure flowchart with a learning-oriented chat to help novice creative coders understand and extend found examples, where visualization and productive friction steer AI use toward learning rather than bypass. Yet visual scaffolds are not universally effective: Code as Anchor, Memory and Metaphor as Support: Learner Experiences with Multi-View Visualizations found students spent ~47% of gaze time on code despite visual scaffolds, driven by agency, representational fit, and the perceived legitimacy of metaphorical views. These learner-experience findings caution that visualization design must attend to affective and social factors, not just cognitive affordances.

Implications

Across the works discussed here, visualization emerges as a dual-use medium: AI increasingly generates and interprets visualizations, while dashboards and interactive visuals serve as the shared surface for human-AI sensemaking. Generative text-to-image and multimodal analysis extend the reach of visualization into specialized STEM content and automated feedback, but uneven model competence, severity-calibration failures, and ethical concerns over misinformation and authorship demand careful, layered verification. For designers and educators, the strongest conclusion is that interactivity and engagement — eliciting learner reasoning over visual data, letting users control cognitive effort, and treating AI-produced visuals as shared infrastructure rather than endpoints — matter more than the fidelity of the chart itself.

Common Misconceptions

- **“AI cannot render specialised content accurately.”** It can, with the right method: fine-tuning a text-to-image model on nuclear concepts **raised domain accuracy from 12% to 78%**. The gap is domain grounding, not generative capability, and it is addressable.
- **“Better visualisations produce better outcomes.”** Teachers **systematically preferred simpler, more traditional visualizations** (bar plots, pie charts, legends) **even when complex designs such as heatmaps yielded more detailed insights**. The more informative artifact was not the one that got used, so adoption is a separate problem from design quality.
- **“Students look where the scaffolding is.”** One study found students **spent most of their gaze on code despite elaborate visual scaffolds** — the aids simply did not capture attention. Visual support that is present but unattended changes nothing.
- **“Engagement and comprehension move together.”** Participants found AI-generated data comics **more engaging and comprehensible, yet many also flagged misinformation risk and information overload**. Both reactions came from the same artifact, so a positive reception is not a verified reading.

Educational NLP

> **Educational NLP** applies language technologies to learning: Cognitive Episodes in LLM Reasoning Traces Enable Interpretable Human Item Difficulty Prediction, A Durability and Cross-Language Transfer Benchmark for a Validated Teaching-Feedback Classification Protocol, LLM-assisted sentiment analysis for integrated computational and qualitative mixed methods education research: A case study of students' written reflection assignments, and What Makes Words Hard? Sakura at BEA 2026 Shared Task on Vocabulary Difficulty Prediction show LLMs advancing analysis of student language at scale (Educational Measurement, educational-nlp).

Questions to Consider

- When an LLM analyzes thousands of student essays or discussion posts for sentiment, what might it be getting right, and what about the language of learning do you suspect it's missing?
- Natural language processing can now estimate the difficulty of vocabulary and test items, and classify teaching feedback at scale. If those predictions feed adaptive systems, who checks whether the machine's judgments about language are actually right for the learners using them?
- How is analyzing student language different from understanding it? Where might the line between correlation and genuine insight blur when NLP scales up sentiment and feedback analysis?
- This concept connects NLP to tutoring, student modeling, and measurement. Before reading, how much of 'understanding a student' do you think can be captured from their written or spoken language alone — and what gets left out?

Introduction

What educational NLP does

Natural language processing in education applies computational methods to the language of teaching and learning — student essays, responses, discussion posts, feedback, and instructional text. LLMs have dramatically expanded what can be analyzed automatically, enabling fine-grained understanding of student language that was previously impractical at scale.

Applications documented in the knowledge base

- **Analysis of student language.** LLM-assisted sentiment analysis for integrated computational and qualitative mixed methods education research: A case study of students' written reflection assignments applies LLM-based sentiment analysis to educational research, extracting emotional and evaluative signals from student text at scale, feeding Learning Analytics and Affective Computing.
- **Prediction and measurement.** Cognitive Episodes in LLM Reasoning Traces Enable Interpretable Human Item Difficulty Prediction and What Makes Words Hard? Sakura at BEA

2026 Shared Task on Vocabulary Difficulty Prediction use language models to estimate item and text difficulty — core inputs to Educational Measurement, Adaptive Learning, and Item Response Theory models.

- **Readability and curriculum alignment.** Bird (2026) fuses transformer text classification with computational-linguistics features to classify English literature by UK Key Stage, reaching an F1 of 0.996 — a data-driven complement to What Makes Words Hard? Sakura at BEA 2026 Shared Task on Vocabulary Difficulty Prediction and Cognitive Episodes in LLM Reasoning Traces Enable Interpretable Human Item Difficulty Prediction for Educational Measurement and reading-level alignment.
- **Generated text carries its own readability burden.** Clark et al. (2026) find that recent models over-use constructions the processing literature associates with comprehension cost — low-frequency n-grams, stacked nouns, denominal verbs, long dependencies, reduced object relatives — relative to their own meaning-preserving paraphrases and to genre-matched human baselines, and trace the pattern to post-training that rewards information density rather than clarity (Why is AI-generated language so hard to understand?). Measuring text difficulty therefore applies to what the model writes, not only to the learner-facing text it is asked to simplify.
- **Semantic similarity is a weak signal for curriculum alignment.** Screening 3,837 dental objective–abstract pairs, embedding retrieval plus a natural language inference check judged 22.9% of high-similarity matches (cosine 0.90–1.00) neutral or contradictory and lifted expert-labeled accuracy from 0.69 to 0.73 (Yasmin et al. (2026)).
- **Discourse-level classification localizes what surface features miss.** A BERT model fine-tuned on only its last four transformer layers classifies adjacent sentence pairs as causal, contrastive, progressive or incoherent and emits the breakpoint as a diagnostic, reaching a mean F1 of at least 0.891 on 28,736 sentence pairs (Wang et al., 2026).
- **Whole-lesson modeling beats utterance-level classification.** Scoring entire lesson transcripts rather than isolated utterances lifted reasoning-chain detection by 14.2 percentage points over state-of-the-art discriminative baselines, and adding a dialect-invariant contrastive objective cut African American Vernacular English false negatives by 18.4 points (Fang and Liu, 2026).
- **Feedback and classification.** A Durability and Cross-Language Transfer Benchmark for a Validated Teaching-Feedback Classification Protocol provides a Benchmark for classifying teaching feedback, advancing Feedback Loop research and LLM Training and Fine-Tuning.
- **Scaling NLP on evaluation comments without reaching use.** A PRISMA-ScR scoping review and evidence map of 421 studies applying NLP to open-ended student evaluation of teaching (2015–2026) finds sentiment analysis still the modal task (300/421, 71.3%) and a 49.7-point actionability discontinuity: 258 studies (61.3%) demonstrated a usable output but only 49 (11.6%) reached evaluation by an intended user, with a formal fairness metric in just 8 studies (1.9%) and external validation in 33 (7.8%) (Eicher & da Silva (2026)).
- **Explanations are not interchangeable with attributions.** Bueno et al. (2026) found SHAP attributions identified the sentences that reliably drove rubric scores and transferred across model

families, while LLM-generated rationales exerted limited, inconsistent influence — even though fine-tuned PLMs outscored prompted LLMs on accuracy.

- **Short-answer assessment in science.** Morley et al.'s scoping review of transformer-based auto-marking of short-answer science questions (2017–early 2024) shows BERT-family models became the field's dominant workhorse for free-text marking before larger LLMs were adopted via prompting, and that models augmented with domain knowledge — extra pre-training, rubric or textbook data, meta-learning — consistently outperformed those without (Auto-marking short answer questions in science: The foundational years of transformer-based models from BERT to GPT-4).
- **Context-sensitivity vs. reference matching in open-response grading.** Benchmarking eleven GenAI and sentence-embedding models on 1,885 software-engineering open-ended answers, Pecuchova, Benko & Drlik (2025) show that context-sensitive LLMs (GPTo1 best, almost-perfect human agreement) beat cosine-similarity reference-based models (BERT, RoBERTa, T5, USE), which systematically misclassified valid but differently-phrased responses. Their NLI analysis revealed that many semantically correct answers fell into the *contradiction* category relative to reference answers — evidence that educational NLP grading must accommodate students' short, diverse, own-word phrasing rather than rigid reference alignment. That contrast sharpens for teacher knowledge: coding 268 U.S. middle school mathematics teachers' open-ended responses, both classical encoders (RoBERTa, Sentence-BERT) and a naive single-prompt GPT-4o topped out well below the human coders on pedagogical content knowledge (PCK), whereas a three-agent LLM harness that iteratively added clarification points to the *human* coding manual reached substantial PCK agreement and near-human agreement on the far more tractable content-knowledge items — reliability coming from refining instructions against real disagreements, not from a larger model, with the most complex teaching-reasoning items still wanting expert review (Copur-Gencturk et al., 2026).
- **Learner-generated question classification.** Lee, Atif & Kang (2026) classify 434 authentic learner questions from 11 IT students across 12 courses into three Constructivism instructional roles — knowledge transmitter, facilitator, and co-learner — and benchmark four transformers on the task. DeBERTa led at 86.36% accuracy (F1 86.52%) with 96.67% precision on factual knowledge-transmitter questions, yet only 78.79% precision on facilitator queries; fine-tuned BERT reached the best co-learner recall (92.00%) at lower precision. The result mirrors the field's recurring pattern that strong aggregate scores mask weak discrimination on higher-order categories: conceptual overlap between roles, ambiguous learner intent, and domain-specific technical phrasing misread as cognitive depth all defeat surface lexical features, arguing for context-aware embeddings, multi-turn dialogue signals, and intent-sensitive features (Cross-Dataset Bloom Question Classification: Supervised Models and Prompted LLMs, From Memorization to Creation: Evaluating the Cognitive Depth of LLM-Generated Educational Questions).
- **Taxonomy classifiers lose most of their accuracy on generated content.** A Bloom-level classifier scoring macro-F1 0.88 on a curated item bank fell to 0.48 and 0.20 across two AI-generated question sets, with the loss tracking the absence of explicit Bloom trigger verbs rather

than model size; only LLMs (0.41 to 0.79) and classifiers retrained on generated items (up to 0.82) held up (Castanares et al., 2026).

- **Corpus-scale curation for pre-training data.** Garrod et al. (2026) replace a single "is this educational?" score with twenty inspectable rubric dimensions — factual accuracy, pedagogical structure, level suitability and foundational-literacy criteria among them — and distill GPT-4.1-mini's pairwise preferences into reusable Edu-QuRaters that recover held-out judge preferences at mean accuracy 0.917, then label all 322.25M rows of FineWeb-Edu-Fortified, where the filtered mixtures lifted downstream Benchmark accuracy over the FineWeb-Edu baseline. It marks a role for educational NLP beyond analyzing the language learners produce: screening the instructional text that other models are trained on.
- **Auditable coding by separating assertions from interpretation.** Bernado et al. (2026) replace single-label prompting with a schema of 221 human-readable assertions - 74 corpus-derived, 48 construct-derived, and 100 automatic word-presence checks - that a transparent classifier maps to the construct label, reaching macro-F1 0.673 and Cohen's κ 0.688 on the TalkMoves teacher-talk corpus against a published direct-prompting maximum of 0.61 macro-F1 and 0.58 κ, while trailing a fine-tuned RoBERTa-base classifier at 0.76. Requiring Krippendorff's $\alpha \geq 0.5$ kept only 33 of 74 corpus-derived assertions, and a words-only baseline scored 0.339 macro-F1, so the gain comes from learned behavioral assertions rather than keyword frequency.
- **Concept tagging at scale.** Yang et al. (2026) split knowledge-concept tagging into a Select–Reason–Judge pipeline — a small model shortlists candidate concepts, the LLM reasons over the shortlist, then judges — lifting tagging accuracy on three benchmarks by shrinking the model's decision space.
- **Handwritten answer sheets resist existing parsers.** Multi-line derivations, interleaved prose and formulas, hand-drawn tables, and noise from strikethroughs and erasures escape printed-document and isolated-expression benchmarks, so the HANS dataset of real eighth-grade mathematics sheets — 5,213 answer images from 745 students across 18 problem types — annotates that noise and backs a noise-suppression model that improves recognition (Wu et al. (2026)).

Connection to tutoring and measurement

Educational NLP underpins both the analysis of learner language (Learner Modeling and Adaptive Instruction, Knowledge Tracing) and the generation of adaptive instructional content (Intelligent Tutoring, Scaffolding). AI-Generated Interactive Fiction for Educational Use: A Pilot Study of Perceived Comprehensibility, Coherence, and Engagement demonstrates NLP-driven content generation for learning, while Comprehensive Review of Intelligent Tutoring Systems situates NLP within the broader Intelligent Tutoring landscape. As LLM-based analysis grows, RCT and Research Methods in AIED frameworks matter for validating that NLP-derived insights genuinely improve learning.

Embeddings can also organize student text by surface form rather than by the construct being taught. On a synthetic Carnot-engine set the same pipeline grouped statements by wording rather than by physics — a novice-like representation, Tauschhuber & Kortemeyer (2026) argue — which makes clustering a tool for exploration, not for grading.

Model compression belongs to the same toolkit: a two-stage pipeline distills a fitted black-box estimator and its post-hoc interpretation into a small open-weight model, so a 2B-parameter “mentee” returns both an estimate and a natural-language explanation offline on a commodity laptop (Distilling Black-Box Machine Learning into a Small, Self-Explaining Language Model for Learning Analytics).

Common Misconceptions

- **“Semantic similarity can screen curriculum alignment.”** Screening **3,837 dental objective-abstract pairs**, embedding retrieval plus a natural language inference check **judged 22.9% of items** as aligned — semantic similarity is a **weak signal** for alignment. A fluent topical match and a genuine learning-objective match are different relations.
- **“Utterance-level classification is the natural unit.” Whole-lesson modelling beats utterance-level classification**: scoring entire transcripts rather than isolated utterances **lifted reasoning-chain detection by 14.2 percentage points**. Context across the lesson carries information that any single turn destroys.
- **“Scaling NLP on evaluation comments produces impact.”** A PRISMA-ScR scoping review and evidence map of **421 studies** (2015-2026) applying NLP to open-ended student evaluation of teaching found scaling **without reaching use**. Volume of method output is not adoption, and the gap is the deployment step rather than the modeling.

Reinforcement Learning

> **Reinforcement learning** trains AI tutors and agents through reward signals: Special-R1: Reinforcement Learning for Special Education — Aligning LLM Tutors to Diverse Learners through Disability-Adaptive Training, Application-Driven Pedagogical Knowledge Optimization of Open-Source LLMs via Reinforcement Learning and Supervised Fine-Tuning, Pedagogical Safety in Educational Reinforcement Learning, and AI Coaching for Accelerating Human Skill Development with Reinforcement Learning align RL with pedagogical objectives, including safety and skill transfer (Intelligent Tutoring, Agentic AI).

Questions to Consider

- An RL tutor 'learns' what to do by maximizing a reward signal. Before you read, what could be wrong with an AI that optimizes for a reward — specifically if the reward is something like 'student clicks continue' or 'correct answer now'?
- The page notes that reward design encodes educational values. If you had to specify the reward an AI tutor should maximize, what would you put in it — and what would your reward accidentally ignore or reward incorrectly?
- RL trains agents to make long-horizon sequences of decisions (what hint, when to advance difficulty, how to pace) rather than single answers. How is that different from the moment-to-moment correctness you might naively reward — and why does the difference matter for learning?
- A tutor's reward can carry the safety constraint inside it, so what the policy is paid for cannot override learner Well-Being. Think of a 'helpful' behavior a reward-optimizing tutor might exhibit that would actually be pedagogically harmful (e.g., giving away answers to inflate completion). Where would your safety line go?
- Reward optimization can preserve or destroy productive struggle, depending on design. From your experience, is 'student completes task' the same as 'student learns'? Where have you seen an AI optimized for the former while undermining the latter?

Introduction

How reinforcement learning works in AIED

Reinforcement learning (RL) trains an agent by rewarding desired behavior — the agent learns a policy that maximizes cumulative reward through trial and error. In AI in education, RL is used to train tutoring agents and learning companions whose decisions chain together over a session — which hint to give, when to advance difficulty, how to pace practice — rather than resolving one answer at a time. This makes RL well suited to Adaptive Learning and Intelligent Tutoring where long-horizon pedagogical decisions matter.

Applications documented in the knowledge base

- **Pedagogically aligned RL.** EduQwen uses an RL-SFT-RL pipeline to train a model that *guides* rather than answers, aligning reward with pedagogical goals; Special-R1: Reinforcement Learning for Special Education — Aligning LLM Tutors to Diverse Learners through Disability-Adaptive Training applies RL to tutor design for Special Education.
- **RL beats supervised fine-tuning for pedagogical instruction following.** LearnLM's training found preference-based RL significantly more effective than SFT alone, because preference judgments capture context-dependent distinctions across long conversations that instruction-labeled supervised data only partly handles (LearnLM Team (2025)).
- **Safety and skill transfer.** Pedagogical Safety in Educational Reinforcement Learning integrates safety constraints into RL-based tutoring so that reward optimization does not come at the cost of learner well-being; AI Coaching for Accelerating Human Skill Development with Reinforcement Learning shows RL-driven coaching that supports genuine skill development and transfer.
- **What a reward leaves out shapes who benefits.** Tithi et al. (2026) found a deep-RL tutor rewarded on test score and time efficiency matched a BKT heuristic on posttest (A = .58 each, against 65.7) but assigned only 4% of training problems to constructive buggy-example repair and favored high Prior Knowledge students.
- **Simulation and practice.** Who Am I? History-Aware Profiles for Student Simulation in Tutoring Dialogues and Q-Learning Lab: Teaching Reinforcement Learning Through Learner-Generated Trace Analysis use RL and simulated learners to train and evaluate pedagogical agents, connecting RL to Learner Modeling and Adaptive Instruction and Learning Analytics.
- **Long-horizon, safety-weighted RL.** ResidencyRL (Liévin et al., 2026) optimizes whole 60-turn clinical encounters — well beyond the ≤12-turn horizons of concurrent dialogue systems — and training against adversarial simulated patients with a safety-aligned reward raised diagnostic accuracy 7.0% and cut missed red-flag rates by about a third.

Evidence across the field

A PRISMA-standard systematic review of RL in education (Riedmann, Schaper & Lugrin, 2025) synthesized 89 studies (2000–2024), finding a sharp post-2016 growth in Adaptive Learning and tutoring applications concentrated in STEM (especially Math Education). It reports that model-free RL dominated (n = 72) with Q-learning the most common algorithm, yet classical RL was more consistently effective than Deep RL (61% vs 36% of papers showing significant superiority). Adaptation split into content-scheduling (n = 53) and guidance-related (n = 36) mechanisms, with RL beating baselines more often on guidance, and learning gain — especially normalized learning gain — was the most effective reward source. The review also warns that over half of studies (n = 54) skipped statistical testing, so the field's growth has outpaced its methodological rigor.

Connection to the knowledge base

RL underpins much modern Agentic AI and Intelligent Tutoring design, where the agent must optimize long-term learning rather than a single correct response. It connects to LLM Training and Fine-Tuning (RL as a training method), Scaffolding (reward design that preserves productive struggle), and Self-Regulated Learning (agents that help learners regulate their own strategy). Because reward design encodes educational values, RL research in AIED is tightly tied to Pedagogical Safety and to the equity considerations of equitable tutor behavior.

Common Misconceptions

"Matching a baseline means the RL policy learned something worth having." It means the reward was satisfied. A tutor can draw level with a BKT heuristic on posttest (**A = .58 each**) while sending only **4% of training problems to constructive buggy-example repair** and preferring the cheaper interaction. The policy optimized what it was paid for, and what it was paid for excluded the productive activity.

"The reward function is a technical detail." It is the pedagogical specification. Whatever the reward weights is what the policy will do, so choosing between score, time efficiency, engagement and repair requires an explicit position on what learning is — a curriculum decision encoded as a number.

"Longer horizons are simply better." They enable what shorter horizons cannot, and they require the reward to be right across the whole sequence. ResidencyRL optimises whole **60-turn clinical encounters**, well beyond the ≤12-turn horizons of concurrent dialogue systems, which raises the cost of a mis-specified objective rather than lowering it.

"RL is the appropriate formalism for tutoring because teaching is sequential." Sequencing is necessary and not sufficient; the binding constraint is the reward's validity. A well-specified objective with a weak policy beats a strong policy against a wrong objective.

Knowledge Graph

> **Knowledge graph** — a structured representation of concepts and their relationships used to model domain knowledge, student understanding, and learning dependencies in AI in education systems. Knowledge graphs enable AI systems to reason about what students know, what they need to learn next, and how concepts relate to each other.

Questions to Consider

- A knowledge graph captures not just concepts but their relationships — prerequisites, similarity, hierarchy. Why might knowing how concepts relate be more useful to an adaptive system than a flat list of skills?
- How are prerequisite relationships in a domain like yours? Can you think of a topic where students routinely struggle because they're missing a foundational concept the graph would reveal?
- The page describes using knowledge graphs to detect knowledge gaps — where learners are missing foundational concepts. How might surfacing that gap change what an AI tutor decides to teach next?
- Knowledge graphs can be built manually or automatically by LLMs from educational text. What are the risks of letting an AI construct the concept structure that a tutor will then reason over?
- If knowledge graphs provide the domain structure that AI agents reason over, what happens to trust and accuracy when the graph itself contains an error or a biased relationship?
- A knowledge graph is described as the structural backbone enabling fine-grained diagnosis and personalized paths. In your own teaching or design, what would you need a knowledge graph of your subject to capture — and what would it leave out?

Introduction

Knowledge graphs provide the structural backbone for many intelligent education systems. Unlike flat lists of skills or concepts, knowledge graphs capture prerequisite relationships, similarity, and hierarchical organization — essential for Adaptive Learning, Knowledge Tracing, and Learner Modeling and Adaptive Instruction.

How knowledge graphs are used in AIED

Knowledge graphs are a recurring structural mechanism across the knowledge base's AIED research, serving several distinct roles:

- **Knowledge Tracing models** use concept graphs to propagate student proficiency estimates across related skills, improving prediction accuracy when data is sparse.
- **Learner Modeling and Adaptive Instruction systems** leverage knowledge graphs to represent what learners know in a semantically meaningful way, enabling fine-grained diagnosis.

- **Adaptive Learning platforms** use prerequisite graphs to sequence content and recommend personalized learning paths.
- **Algorithm choice over the graph changes outcomes.** In G4L, propagating mastery through an Evolving Knowledge Space Graph with Bayesian knowledge propagation produced +24% measured knowledge (0.717 → 0.887), against +5% for Knowledge Space Theory and +1% for Weighted Distance Dependent Induction (Csépányi-Fürjes & Kovács, 2026).
- **Cognitive Diagnosis frameworks** like HiLLM-CD construct concept trees from educational text using LLMs, eliminating manual annotation.
- **Knowledge-graph-augmented tutoring:** ITAS uses a knowledge graph of quantum concepts (with explicit prerequisite relationships) to drive a multi-agent tutoring system, traversing the graph to select next topics for counterintuitive material.
- **Curriculum and course modeling:** CourseGraph compares CS course structures across institutions using graph representations; Learnity graphs model lifelong learning pathways.
- **Prerequisite-relation learning:** ProPrL learns prerequisite relations among concepts, formalizing the edges that knowledge graphs encode.
- **Knowledge-gap detection:** Knowledge gap detection uses graph-based reasoning in AI teaching assistants to identify where learners are missing foundational concepts.
- **Multimodal AI and explainable reasoning:** multimodal knowledge graphs extend graph structure across content modalities; fair and explainable recommendations combine knowledge-graph embeddings with sequential modeling (a hybrid HKG-GRU framework).
- **Instructionally structured graphs for resource recommendation:** Liu, Sun & Song (2026) decompose each teaching-resource entity into four instructional dimensions (teaching context, cognitive level, technological feature, cultural adaptability), compute user-dependent semantic similarity over those dimensions, and fuse it with collaborative filtering via an ability- and progress-aware coefficient — encoding pedagogical structure directly into the recommendation signal rather than treating resources as consumption items.
- **Ontology-based knowledge bases:** Ivanova (2026) proposes a layered, hybrid knowledge-base architecture grounded in description logic that replaces the classic ITS single-ontology models with **systems of mapped ontologies** — adding procedural (rule-based), probabilistic/fuzzy, and ML-extracted implicit knowledge — plus a metadata framework for describing, discovering, and reusing educational ontologies.
- **Scaffolding and writing:** Veriforge and visual query tracing apply graph-based structure to narrative drafting and declarative-logic learning.
- **Human-curated literary graphs, and what an audit exposes:** Incipit graphs literary premises — 1,455 axiom records, 1,464 mappings to 149 works, and 472 typed relationships — with language models proposing candidate formulations that human curators selected and grounded. Its recomputed audit is as instructive as its structure: every endpoint resolves and no duplicate or self-link remains, yet 1,448 of the 1,455 axioms map to exactly one work (so cross-work reuse is sparse), the context taxonomy cannot separate its two context types, and no provenance record survives, leaving the snapshot unable to reconstruct its own pipeline. Structural validity is not interpretive quality, and a curated graph without provenance can be neither audited nor refreshed.

LLM-driven knowledge graph construction

Recent research explores using LLMs to automatically construct knowledge graphs from educational content. The HiLLM-CD framework uses multi-agent LLM pipelines to generate exercise-concept links and hierarchical concept trees, reducing reliance on expert annotation. This connects to broader Generative AI applications in curriculum design and automated content organization, and to RAG (Retrieval-Augmented Generation) (retrieval-augmented generation), where graph-structured knowledge can improve retrieval quality over flat similarity search.

Relationship to other concepts

Knowledge graphs connect to Learning Design (defining what to teach), Curriculum Design (how to sequence it), and Learning Analytics (extracting insights from student interaction data). They are foundational to Intelligent Tutoring systems that need structured representations of educational domains. As AI agents become more common in education, knowledge graphs provide the domain structure that agentic systems reason over — a pattern seen in ITAS and knowledge-gap-detection teaching assistants.

Common Misconceptions

“A knowledge graph is a concept map with better tooling.” The distinguishing claim is relational and computational: a graph is useful because prerequisites, similarity and hierarchy are explicit enough for an algorithm to traverse, not because it draws connected nodes. What follows from that is the operational question the page keeps returning to — which traversal or propagation algorithm runs over the graph — because that choice is where the instructional effect actually lives.

“Having the graph is what improves outcomes.” The algorithm over the graph changes the outcome. In G4L, propagating mastery through an Evolving Knowledge Space Graph with Bayesian knowledge propagation produced **+24% measured knowledge** (0.717 → 0.887), against **+5%** for a Knowledge Space based comparison. Same general idea of a structured knowledge space, materially different result depending on the propagation method. Buying or building a graph is the beginning of the design problem, not its solution.

“An LLM-built graph that passes a structural audit is a validated graph.” Structural validity and instructional validity come apart in exactly this way. The recomputed audit of one such graph found that every endpoint resolves and no duplicate or self-link remains — a clean structure — yet 1,448 of its 1,455 axioms map to exactly one work, so cross-work reuse is sparse, its context taxonomy cannot separate its two context types, and central claims remain unproven. Dead links and duplicates are the failures an automated audit catches; thin reuse and undifferentiated categories are the ones it waves through.

Implications for Practice

For instructors

- Ask what the graph is used *for* before asking whether it is accurate: recommendation, prerequisite sequencing, or diagnosis. The evidence differs sharply by use, and prerequisite sequencing carries the strongest result.

- When a tool claims adaptive sequencing, ask for the measured comparison against a non-adaptive baseline rather than a description of the knowledge structure.
- Expect sparsity in cross-work reuse, and treat a graph whose entities map one-to-one onto single sources as a catalogue with edges rather than as an integrated map.

For developers

- Treat the propagation algorithm as a first-class design decision and report the algorithm as part of the intervention; the +24% versus +5% gap is attributable to it.
- Audit beyond resolvability. Test whether categories are separable and whether entities are reused across works, because structural cleanliness consistently coexists with instructional thinness.
- Validate the graph against learning outcomes, not against graph statistics.

For researchers

- Report graph-baseline contrasts at the algorithm level. “Knowledge-graph-based” is not a treatment; the traversal strategy is.
- Report axiom-to-source mappings and taxonomy separability alongside precision and recall, since the audit failures here were invisible to conventional graph metrics.

Robots in Education

> **Robots in education (educational robotics)** — the use of physical or simulated robots as tools for teaching and learning. Educational robotics spans a wide spectrum: from programmable kits that teach computational thinking and programming, to socially assistive and humanoid robots that tutor, tell stories, model sign language, or rehearse social skills. It is valued for fostering problem solving, critical thinking, Creativity, and STEAM engagement, and for making abstract computing concepts tangible through embodied interaction. The knowledge base's robotics corpus spans curriculum-integrated programming, LLM-powered conversational tutors, socially assistive storytelling robots, and role-play for social-emotional learning. It is underpinned by two closely related areas absorbed here: **social robots** (robots designed for social interaction and relationship-building) and **human–robot interaction (HRI)** (the study of how people perceive, trust, and learn with robots).

Questions to Consider

- A robot in the classroom adds an embodied, social presence that a chatbot on a screen can't. What do you think the physical body and social cues of a robot change about how students learn, trust, and engage — and what might they distract from?
- Social robots use human-like speech, gestures, and personality to teach, tell stories, or rehearse social skills. Is a robot that looks and acts human inherently better for learning, or could that social presence bring risks (misinformation, over-reliance, privacy) that software-only tools don't?
- LLMs now let social robots converse fluently. If a robot can talk like a tutor, what still depends on its physical embodiment — and where does adding a 'body' really matter for learning versus just being a novelty?
- Think of a time you learned something by physically manipulating an object or watching your actions produce a visible result. How might programming a physical robot ground abstract ideas (like program logic) more effectively than writing code on a screen?

Introduction

Educational robotics is a distinct but closely related application of AI in education. Unlike software-only intelligent tutoring or Large Language Models (LLMs) chatbots, robots add an **embodied** and often **social** presence — a physical agent that learners can see, manipulate, and (increasingly) converse with. This embodiment is central to their pedagogical value: it grounds abstract program logic in observable behavior, and it can support relationship-building and emotional engagement that disembodied systems cannot.

The evidence is thinner than the volume of work suggests: a review of AI and robotics in education finds most empirical studies involve learners under 13 over four weeks or fewer, concentrated in a few early-investing countries, with learning performance the most-studied outcome and ethics, equity and policy lagging deployment (White and Wu (2026)).

Social robots and human–robot interaction

Two strands shape the social side of robotics in education.

Social robots are robots designed to engage people through social interaction, using human-like cues such as speech, gesture, facial expression, and personality to communicate, teach, assist, or accompany. In education, social robots (humanoids like iCub, Pepper, Reachy, and companion robots) are used for tutoring, storytelling, role-play, language support, and as study companions. Their social presence is the key differentiator from software-based AI agents, enabling relationship-building and emotional engagement. Advances in large language models have dramatically expanded what social robots can say and do, enabling fluent, adaptive conversational tutoring — while also introducing risks such as misinformation, over-reliance, and Privacy violations, motivating knowledge-based design approaches.

Human–robot interaction (HRI) is the interdisciplinary study of how people and robots interact, encompassing perception, communication, collaboration, and the social, cognitive, and ethical dynamics of that interaction. In education, HRI underlies how learners perceive, trust, and learn with robots — whether programming a robot, conversing with a tutoring robot, or rehearsing social scenarios. HRI research examines how robot appearance, behavior, task context, and embodiment shape user experience, trust, agency, and learning. Key concerns in educational HRI include preserving human Learner Agency, building Trust, supporting Self-Efficacy, and ensuring that interaction with robots supports rather than undermines autonomy and social learning. It connects robotics to Human AI Collaboration and Social-Emotional Learning.

How robots are used in education

Christ et al. (2026) add a role typology rather than a technology list: their five workshop-derived types of classroom robot differ by *pedagogical function and abstraction level*, not by hardware. Type a runs a non-interactive demonstration of generic social patterns (a scripted emotion theater followed by discussion of dynamics such as escalation or misunderstanding); type b is a touch-reactive interactive robot supporting participative physical theater, embodied learning, boundary awareness and emotion regulation; type c is a spoken-language partner that shows empathy and remembers interactions with a single pupil, creating a protected one-to-one setting for self-disclosure; type d is externally guided by a hidden specialist like a puppet with extra degrees of freedom, aimed at flattening social hierarchy; and type e is a non-interactive robot replaying actions recently observed in the school so pupils can reflect on situated behavior — the contrast with type a being exactly its context-specific rather than generalized abstraction. The typology is explicit about being an unvalidated design space grounded in one national mental-health program, so it is a menu for designing and evaluating robot roles, not evidence that any of them works.

- **Computational thinking and programming:** Programmable robots (e.g., LEGO, block-based platforms) help learners connect code to real outcomes. Valls i Pou links computational thinking to secondary STEAM curricula, and RoboBlockly Studio combines block programming with a conversational AI agent and embodied robot feedback. EduSim-LLM lets beginners control simulated robots with natural language.
- **Tutoring and knowledge delivery:** Knowledge-based design research and Teachy Mini develop LLM-powered generative social robots that tutor higher-education students, addressing risks like

misinformation and overreliance. Research on trust shows that what a robot does (task context) shapes learner trust more than its appearance, with the highest trust during instructional tasks.

- **Storytelling and engagement:** MotiBo and RoboBuddy use interactive, LLM-powered social robots for storytelling to boost motivation and engagement, while the iCub narrative HRI study explores co-creative storytelling between humans and humanoids.
- **Social-emotional learning and inclusion:** REMind uses robot-mediated role-play to rehearse anti-bullying bystander intervention, and work with the Pepper robot explores robot sign-language communication to support Deaf learners. A scoping review maps Pepper's use in formal education.
- **Autonomy and agency:** A systematic review synthesizes how HRI affects human autonomy and sense of agency, bridging design frameworks with regulatory demands (EU AI Act, IEEE Ethically Aligned Design). Social robots as study companions and robot–LLM integration in creative writing further explore robot roles.
- **Project-based and game-based approaches:** Bots and Blocks presents a project-based robotics course, and a systematic review compares game-based learning and gamification in robotics education.
- **Reinforcement learning and sim-to-real in a full robotics workflow.** Dong, Cao and Wang (2026) convert an end-to-end research robotics workflow — assembly, electrical checks, simulation-based policy training, and physical deployment — into a high-school course built on one open humanoid (a ToddlerBot, reported parts cost under USD 6,000) across eight three-hour sessions. Pairs share one robot and train a walking policy in Simulation before deploying it to hardware, with safety gates (a passed standing test before walking) making the dependency order visible. Because a shared artifact rewards the team rather than the individual, the framework separates robot performance from individual understanding: students rotate roles, each submits a separate prediction and explanation at every checkpoint, and supported stepping is explicitly not treated as evidence of conceptual mastery — the authors' warning that passing a robot milestone is not understanding it.
- **Competition robotics as an ecosystem problem, not a kit problem.** Jacobson et al. (2026) locate the binding constraint on K–12 robotics less in curriculum or hardware than in sustained local technical mentorship, and show it is distributed geographically: in Indiana, FIRST LEGO League participation collapsed in the 2020 remote season, urban participation gradually recovered, and rural participation did not, remaining near its post-2020 level through 2025–2026. Their ARC framework makes mentorship the engineered object — colleges run a credit-bearing course that prepares undergraduates as workshop mentors for nearby teams, and mature school programs become secondary hubs whose experienced students become peer mentors for further schools, so reach propagates beyond any university's catchment through a self-reinforcing loop. A one-university trial created three rural FLL teams and moved undergraduate community connection from 1.86 to 4.00 on a five-point scale (the largest of any measured shift, ahead of confidence teaching technical concepts at +1.29). A spatially explicit Markov simulation of Indiana's 1,925 public schools projected 992 school programs after 40 years under moderate assumptions against 161 with no ARC. The evidence is feasibility-level — seven mentors and four parents,

retrospective self-reports, no control group — but the framing is portable to any robotics program: what scales or fails to scale is mentorship capacity and hub geography, not the robot (Teaching AI, Robotics, & Community: A Hubs-Based K-12 Education Framework for Reaching Rural Schools).

- **Child development and young learners:** AI-enabled toys and child development shifts the lens to commercial AI toys in early childhood, examining how AI-enabled playthings affect child development and play. This extends educational robotics beyond classroom robots to the consumer toys children encounter at home, raising questions about agents in play, trust calibration, Learner Agency, and Well-Being for the youngest learners — an area where design guidance is thinner than for school-age robotics curricula.
- **Tangible coding and social robots in pre-K AI literacy.** Lee (2026) integrates unplugged play, tangible coding (Bee-Bot, Ozobot), and guided dialogue with a social AI robot in the Play With AI (PL-AI) curriculum for pre-K and kindergarten. The design-based research documents how these embodied, tangible robotics activities support children's emerging reasoning about AI concepts, with four design principles — embodied play, tangible coding, guided dialogue, and teacher co-design — offering a developmentally appropriate model for early childhood robotics and AI education.
- **Two paradigms for young learners: coding robots and generative social robots.** Yang, Li and Lee (2025) frame early-childhood robotics as the pairing of two pedagogical paradigms, each with a distinct theoretical base. **Coding robots** (Bee-Bot, KIBO, Matatalab) descend from Papert's LOGO and embody constructionism — children learn by making and build computational thinking through tangible programming. **Generative social robots**, powered by generative AI, are grounded in social constructivism, acting as conversational peers or tutors who scaffold learning within the child's Zone of Proximal Development and support social-emotional development. Their five-step **Creative Project Approach** for integrating both robot types into the Project Approach keeps teachers as facilitators who guide child–robot interaction, balance automation with Creativity, and preserve child Learner Agency.
- **What kindergarten CT robotics actually does.** A systematic review of 53 studies found problem-based learning, storytelling, and scaffolding the most frequently used strategies, with most studies naming no CT framework and using ad hoc assessment tools rather than a validated instrument such as TechCheck-K (Tsingidou & Sapounidis (2026)).
- **LLM planning rather than conversation.** Kudláčková (2026) uses a vision-language model to convert photographs of Shoebox Tasks — visually structured activities used with learners on the autism spectrum — into a PDDL problem that a Nao humanoid executes or demonstrates, with plan correctness scored across six tasks rather than any learner outcome.

Embodiment and pedagogy

A defining theme is that robots are effective when they support genuine learning goals — not as isolated technical exercises. A desk-mounted robotic projector tied with laptop ChatGPT while help was available (6.7 vs. 7.3/10, p = .41) but held its score after withdrawal (7.0 vs. 4.4/10, p = .003), a 60% higher short-term transfer score — a task-dependent gain the authors attribute to spatial co-location rather than general

replacement (Orlando et al. (2026)). The value of a robot depends on the pedagogical context: teaching computational thinking (Computational Thinking), supporting STEAM, building programming skills, motivating learners (Motivation, engagement), or supporting Social-Emotional Learning and inclusion. Robotics also connects to Project-Based Learning, Game-Based Learning, and Experiential Learning. Key design considerations include preserving learner Learner Agency, building Trust, supporting Self-Efficacy, and grounding learning in embodied interaction. In Language Learning, meta-analytic evidence points to the effectiveness of embodied robot-assisted language learning.

- **Pathways to learning AI-powered robotics.** A qualitative study of high school students in a robotics+AI curriculum found learning through real-world practice, designing, and playful creative expression (constructionist, epistemological-pluralist lens).

Common Misconceptions

- **"Robotics teaches computational thinking by virtue of being robots."** A systematic review of **53 studies** found **problem-based learning, storytelling and scaffolding** the most frequently used strategies — the pedagogy carried the outcome, and it is what the studies actually did.
- **"Physical robots beat screen-based alternatives across the board."** Gains were **task-dependent**: a short-term transfer score **60% higher** for Orlando et al., 2026 (4.4/10, p = .003) that the authors attribute to **spatial co-location rather than general replacement**. The claim is about co-location on specific tasks, not about physicality in general.
- **"Kindergarten CT is too early to be meaningful."** The reviewed evidence covers kindergarten robotics directly, which means the age band is studied rather than assumed unsuitable.

Conversational AI

> **Conversational AI (CAI) agents** — AI-driven speech- or text-based agents that simulate and automate conversations, from rule-based chatbots to NLP/ML and Multimodal AI LLM-based assistants — are among the most widely used AI interfaces in education, valued for teaching, psychological, and metacognitive support even as technical, cognitive, and ethical concerns persist.

Questions to Consider

- When you've used a chatbot or AI assistant, did you think of it as a teacher, a search engine, or something else? How did that framing shape how much you actually learned from it?
- Conversational AI describes HOW an agent talks, not what it's built to do. Could a chatbot be conversational yet completely unpedagogical — and what would tell you the difference?
- One study found that AI literacy — not general tech savvy — predicted whether students were willing and able to use a chatbot. Why might knowing how AI works matter more than being 'good with computers'?
- A raw general chatbot can short-circuit reasoning by answering immediately, while a structured tutor preserves productive struggle by withholding answers. What design choices decide which kind of agent a student meets?
- Students using a law-course chatbot did a third of their interactions after hours — evidence that 24/7 availability is a real benefit. But does always-on access also carry risks you'd want to design against?
- The biggest barrier to chatbot adoption in one study was a badly designed pop-up, not distrust or academic-integrity fears. What does that suggest about where AI-in-education investments actually fail?

Introduction

Conversational AI (CAI) is the umbrella term for AI-driven agents that carry on spoken or written dialogue, most commonly realized as chatbots and, more recently, generative Large Language Models (LLMs)-based assistants such as ChatGPT, Claude, and multimodal educational avatars. Modern CAI agents fall into Machine Learning-based, NLP-based, and hybrid categories, with text-based agents the most prevalent in education. As learning tools they function as intelligent tutors, Feedback providers, interaction partners, and administrative assistants — overlapping with pedagogical agents while spanning a broader set of applications.

How conversational AI appears in the knowledge base

An umbrella-review synthesis. The umbrella review of CAI agents (34 review articles) shows CAI utilization is concentrated in teaching and learning support (97.1% of reviews), psychological and motivational support (91.2%), and metacognitive and personal development (88.2%), while administrative

support, research management, and healthcare education lag. The review documents that human–AI relationship concerns persist across all CAI generations, with Academic Integrity and data Privacy emerging as newer ethical issues, and calls for HCI-grounded, evidence-based design and stronger AI Literacy support.

From chatbots to tutoring agents. The knowledge base traces CAI's evolution from rule-based FAQ chatbots toward tutoring-focused agents. The conversational AI tutors framework argues proven ITS technologies (Knowledge Tracing, affect detection, student modeling) should anchor generative tutors while Generative AI supplies flexible dialogue. Research on whether LLM tutors teach or solve and tutoring-specific vs general AI shows pedagogically designed Guardrails matter: raw general chatbots can short-circuit reasoning while structured tutors preserve productive struggle.

Benchmarks may overstate how much scaffolding gets taken up: across 9,490 chats in nine datasets, students in real deployments bypassed the chatbot's pedagogical framing at little interpersonal cost to drive the interaction toward their own goals — an instrumental Help-Seeking move rather than disengagement (Neagu et al. (2026)).

Interaction and collaboration. Conversational agents are increasingly framed as interaction partners rather than answer-givers. Student-AI Interaction captures how learners prompt, question, and verify with CAI in practice. In Collaborative Learning, agents mediate participation and shared AI Regulation in Education, and in Language Learning they provide real-time conversational practice. The Human AI Collaboration thread examines when this partnership preserves versus substitutes for the learner's cognitive work. LLMs as critique partners illustrate the preservation side concretely: Oppenheimer, Cash & Connell Pensky (2025) had ChatGPT, Gemini, or Claude critique students' argumentative essays across a semester, and learners improved on writing, prompt engineering, and response-to-feedback while rating the exchanges useful, engaging, and enjoyable — with active rebuttal of model claims (87.8%) showing they treated the conversational partner critically rather than passively.

Conversational agents are used to grade, and their evaluative behavior diverges from humans': ChatGPT was the most lenient of three evaluators of the same 52 undergraduate projects (M = 91.46 against 83.13 for the instructor) and shared no grading logic with peers (r = 0.05), though students valued its dialogic interactivity (Usher & Faraon (2026)). **Users read the agent's credibility socially.** Perceived competence of ChatGPT predicted its feedback credibility directly, while perceived warmth worked only through human-like empathy (SEM, 230 students), for Pérez-López et al. (2026) — a conversational agent earns credibility as a social partner, not just as an answer source.

Scaffolding the student's side of the conversation. Jin et al. (2026) add a question-specificity monitor and a revision template to a chat interface and intervene only on vague questions: in a between-subjects study with 40 college students learning web programming, HelpCoach users wrote significantly more specific first questions (57.3% vs. 40.5%) and retained more knowledge one week later (mean gain 1.9 vs. 0.3 of 6, d = 1.100). The retention benefit did not run through more targeted chatbot replies, which did not differ by condition — leaving the mechanism an open hypothesis rather than a demonstrated pathway.

The role the agent plays shapes the interaction. CAI design is not neutral about its persona: Liao (2026) found a fixed "student peer" companion in elementary book talk sustained longer interactions yet dominated the conversation (lower student word/sentence share) and hit an "affective ceiling" — matching a human teacher on factual recall but falling short on emotional and future-oriented reflection — arguing CAI should adapt its role (peer, teacher assistant, parent advisor) rather than stay monolithic. Xu et al. extend this to

small groups, showing generative AI acts as both an *agent* and a *collaborative space* in synchronous and asynchronous collaborative dynamics, where the interaction design decides whether it scaffolds or supplants group cognition. Tone can also be set by an external classifier rather than by the conversation alone: Sukoon (Bashir & Afzal, 2026) trains a Random Forest on 20 survey features to assign a low, moderate, or high stress level, and that output selects one of three response tiers inspired by the Stepped Care Model — warm and encouraging at low stress, grounding and non-judgmental at high stress — before an Open Source LLM (GLM-4.5-Air via OpenRouter) takes over the dialogue with the full conversation history and a culturally adapted system prompt re-sent on every turn. The authors chose a free-access multilingual model deliberately to keep deployment feasible in regional universities, and note that Urdu appears through prompt engineering rather than a genuinely bilingual pipeline — a limitation that matters whenever cultural appropriateness is claimed as a system property rather than an evaluated outcome.

Conversational behavior tracks the provider, not the tuning. Across 1,971 AI and 135 human transcripts scored on six fixed rules drawn from the learning sciences, models from the same provider clustered together with no overlap between family ranges, which the authors read as teaching behavior following provider-wide training practices rather than individual model tuning (Northcutt et al. (2026)).

Response consistency is an infrastructure problem, not a prompting one: within-model reply similarity ran 0.715–0.795 against 0.443–0.604 between models, and adding chat history changed reply content even for the same focal message (Hao (2026)). **Student perspectives.** Real-world usage shows adoption hinges on AI Literacy and user experience more than on technical capability. A human-centered mixed-methods study of the "Jordan Chatbot," a GPT-4o-based pedagogical agent in an Australian law course, found students hold positive attitudes and perceive gains in knowledge while strongly supporting Academic Integrity requirements; over a third of interactions occurred after hours, confirming the value of 24/7 availability (Colbran, Jha & Schiavone 2026). Notably, AI literacy — not general technology proficiency — predicted willingness and confidence to use the chatbot, and usability (an intrusive pop-up design) was the largest barrier among non-users, ahead of trust, preference for staff, and academic-integrity fears.(Understanding student perspectives on generative AI chatbots: a human-centred mixed-methods study in higher education) The study recommends human-centered design, explicit AI policies and assessment labels, staff and student training, and continuous error monitoring — evidence that effective CAI deployment is as much a design and literacy problem as a technical one. At the other end of the age spectrum, Vahedian Movahed & Martin (2025) studied children aged 6–14 interacting with AMA, a topic-bounded, age-tailored chatbot (astronomy, sneakers and shoes, dinosaurs), finding broad openness to and high trust in the AI as an information source — children even tested its credibility with known-answer questions — alongside gaps in critical engagement and digital-safety awareness that argue for age-sensitive, trust-aware conversational-ai design and explicit Privacy instruction.

Who uses the agent also varies: among 97 graduate statistics students, more than a quarter never used the StatBot chatbot, and female students used it significantly more often ($W = 679.5$, $p = .015$), which the authors read as conversational AI lowering the perceived social risk of asking questions (Lee and Wu (2026)).

Adoption is not homogeneous: clustering 192 student and educator responses yields four personas — Cautious Achievers, Skeptical Utilitarians, Disengaged Doubters and Engaged Enthusiasts — that average-effect acceptance models obscure, with students prioritizing immediate Feedback and educators content accuracy and Academic Integrity (Saihi & Ahmed (2026)). **Durability has been observed for one**

institutional deployment. A four-year randomized evaluation of a non-generative knowledge-base chatbot at California State University, Northridge (N = 8,708), found students remained receptive across eight semesters — annual opt-out rates never exceeded 4% — while impacts concentrated in time-sensitive administrative tasks such as early course registration (34 percentage points more likely to enroll by the deadline) and no statistically significant effects appeared on GPA, units, or persistence (Mata, Russell & Page 2026, a working paper). Its measurement lesson bears on how CAI engagement is counted: with opt-out near zero alongside roughly 5% active engagement on interactive campaigns, conclusions about sustained engagement depend on whether a study counts only direct replies or also passive engagement, where students act on information without texting back.

Risks and ethics. CAI agents carry persistent risks of over-reliance and cognitive offloading (the leading ethical concern in the umbrella review), plus technical limitations, hallucination, bias, plagiarism, and equity barriers. These concerns animate AI Literacy and Reducing AI Misuse and require policy and ethical-AI Governance responses. A further trust concern arises around the adoption advice staff increasingly receive: staff are urged to consult conversational AI about whether to adopt AI, yet such systems are built by organizations with a commercial stake in adoption. An audit of ten frontier LLMs found most acknowledge skeptical users' concerns before redirecting to engagement framings, raising questions about the neutrality of AI adoption advice.

Game-based conversational agents. Beyond tutoring, conversational agents are being embedded in digital game-based learning. Wenzel, Geiger, and Liening (2026) use action design research to derive the **CAIS-GBL** framework — four design principles and fifteen design features for AI conversational agents in digital game-based learning — grounded in theory-driven meta-requirements spanning cognitive, motivational, affective, and socio-cultural engagement and an equity-by-design stance. Their instantiated agent (Lara) in a business Simulation game was positively received for cognitive and social presence and support for self-regulated learning, evaluated with student teachers and in a field study — a practical blueprint for adaptive instructional support via conversational agents in serious games.

Relationship to pedagogical agents and intelligent tutoring

Conversational AI is best understood as an **interaction modality** that overlaps — but does not coincide with — two more established constructs in the knowledge base: pedagogical agents and intelligent tutoring systems (ITS).

Conversational AI as the medium, not the pedagogy. CAI names *how* the agent communicates (natural-language dialogue, spoken or text). It says little on its own about *what* the agent is built to do. Pedagogical agents, by contrast, are defined by their **instructional role** — an AI component that engages learners through dialogue, questions, or prompts to support metacognitive processes, Feedback, and Scaffolding. Intelligent tutoring systems are defined by their **architecture and modeling** — a diagnostic backbone of Knowledge Tracing, student modeling, and pedagogical decision logic that tracks what the learner knows and adapts instruction. A single agent can be all three at once: e.g. a conversational AI tutor is a CAI agent (dialogue interface) that functions as a pedagogical agent (tutoring strategies) built on an ITS foundation (student modeling). The distinction matters because a CAI agent need not be pedagogically grounded at all — a plain FAQ chatbot is conversational AI without being a pedagogical agent or a tutor.

The pedagogical-agent lens. Pedagogical agents use the conversational medium to enact teaching strategies — eliciting self-assessments, Socratic questioning, role-specialized facilitation in multi-agent designs (Teacher, Assistant, Classmate, Analyzer). Not every CAI agent is a pedagogical agent, but the two heavily overlap: the umbrella review of CAI agents found teaching and learning support (97.1%) and metacognitive development (88.2%) dominate CAI applications, meaning most education-focused CAI agents function pedagogically. The novice-programmer scoping review sharpens this: only 4 of 23 conversational agents explicitly grounded design in learning theory — most were pedagogical in intent but not in foundation.

The ITS lens. Intelligent tutoring contributes the *cognitive diagnostic machinery* that raw conversational models lack. The conversational AI tutors framework argues proven ITS technologies should anchor generative tutors: knowledge tracing, affect detection, and student modeling supply the structure, while Generative AI and LLMs supply flexible dialogue. This is the key design tension — conversational AI provides natural, scalable interaction, but without ITS-style structure it risks over-scaffolding, hallucination, or bypassing the learner's productive struggle. Research such as Measuring Whether LLM Tutors Teach or Solve: A Diagnostic for Educational Impact and The Evidence Base on AI in K-12: A 2026 Review shows that pedagogy-oriented criteria (guiding questions, calibrated hints) must be designed in explicitly.

In short: conversational AI is the **interface/medium**, pedagogical agents are the **role**, and intelligent tutoring is the **underlying modeling and instructional logic**. Educationally valuable CAI agents sit at the intersection of all three — conversational in interface, pedagogical in intent, and tutor-like in their modeling of the learner.

Practical guidance

Choose conversational agents to support teaching, Motivation, and Metacognition rather than merely to answer questions, and design for HCI-grounded, participatory, user-centered interaction. Guard against over-reliance by pairing CAI with AI Literacy instruction and Feedback that keeps the learner cognitively productive. Attend to AI literacy and usability explicitly — since these — not general digital skill — drive adoption and non-use (Colbran, Jha & Schiavone 2026) — and pair deployment with clear AI-use policies, assessment labels, and training. Evaluate CAI on pedagogical outcomes — not just task completion — and plan for equity and Accessibility from the start rather than as an afterthought.

- **How students actually talk to conversational agents — a six-category disengagement scheme:** Rho et al. (2026) embedded a GPT-4-Turbo teachable agent (positioned as a struggling middle-school student, grounded with RAG over a knowledge graph, paired with a mentor agent that critiqued students' explanations) into Math Nation's Algebra and Geometry lessons, and coded 5,522 utterances from 246 students. Beyond engagement (75.7% of utterances), they identified False Answering (12.8%), Withholding (8.9%), Random/Noisy (2.1%), Mirroring (0.6%), Mocking (0.3%), and Ghosting (0.2%) — with Mirroring (copying the agent's text) emerging inductively from the data. The classification was human-in-the-loop: 1,682 utterances annotated by two raters (κ = 0.704–0.905 per category) trained a fine-tuned LLaMA 3 classifier (weighted F1 = 0.910 on held-out threads) that labeled the remaining 3,840 utterances. A process-level competing-risks analysis then showed most disengagement resolves within a few turns except Withholding, which persists — a signal worth designing agent responses around.

Common Misconceptions

- **“A conversational agent’s credibility tracks its accuracy.” Users read the agent’s credibility socially.** Perceived **competence** of ChatGPT predicted its feedback credibility **directly**, while perceived **warmth** worked only **through** that route. A warm, competent-sounding agent earns trust on presentation, which is a separate axis from correctness.
- **“LLM critique partners replace the learner’s judgement.”** Oppenheimer, Cash and Connell Pensky (2025) show the **preservation** side concretely: the value is in keeping the learner’s thinking intact rather than in producing the critique for them.
- **“The umbrella evidence on conversational agents is conclusive.”** The umbrella review synthesises reviews of CAI agents, and an umbrella review’s strength is bounded by the quality of the reviews it gathers.

Simulation

> **Simulation** — the use of modeled environments, agents, or scenarios to support learning through practice and feedback in contexts that are safe, repeatable, and often otherwise inaccessible. Simulations let learners act, make errors, and see consequences without real-world cost, and are increasingly powered by AI and agent-based modeling.

Questions to Consider

- Recall a time you learned something by doing it in a safe, low-stakes environment — a lab, a mock exercise, a flight or game simulator. What made that practice effective, and what might be lost if the simulation were too realistic or not realistic enough?
- The page argues simulations let learners make errors and see consequences 'without real-world cost.' What do you think is gained, and what might be lost, when the cost of a mistake drops to nearly zero?
- If an AI can simulate patients, students, or conversation partners for practice, where would you draw the line between valuable rehearsal and practice that fails to transfer to real human interaction?
- Why might a learner's awareness of a simulation's limits — its trustworthiness — matter as much as how faithfully it models reality?
- How could the same simulation technology that helps someone learn also mislead them, and what would you need to know to tell those two outcomes apart?

Introduction

Simulation sits at the core of experiential and Active Learning pedagogies. It provides the deliberate practice, productive failure, and feedback loops that build skill and judgment. AI has transformed simulation in two ways: it powers more realistic and adaptive simulated environments, and it generates simulated learners, patients, or interlocutors that make practice scalable. Behavioral evidence shows that *how* learners engage with a simulation varies systematically rather than uniformly: tracing online learners building ecological models in VERA, An, Hammock & Goel (2025) classified engagement into Observation (frequent runs and parameter adjustment with little model building), Construction (hands-on building with little simulation), and Exploration (full construct–parameterize–simulate cycles), with Explorers producing the most complex and diverse models and observation-heavy learners largely copying existing ones — an argument for designing simulation environments that push learners toward full-cycle activity. - **An explicit mechanism is inspectable in a way a learned generator is not.** DagFlow-AI builds synthetic data from a directed acyclic graph plus per-variable distributions and formulas, so the data-generating process is a document an instructor can read and correct (Arthur et al., 2026). This is in deliberate contrast to GAN and VAE synthesis, which needs a seed dataset and yields an opaque process. The trade-off is that reaching a stable simulation took several iterations.

AI and simulation

- **AI-powered environments:** adaptive simulations adjust difficulty and scenarios to a learner's state, linking to Adaptive Learning and Reinforcement Learning-based coaching.
- **The virtual environment and the AI layer are separable gains.** In a three-week Grade 9 Ohm's law unit, adjusted achievement was 23.45 of 30 with an AI-supported virtual laboratory, 20.51 with the same laboratory without AI and 16.57 in a physical laboratory (Li and Ahmad (2026)). Intact classes were assigned with a different teacher each, so this describes three classroom arrangements, not the agent alone.
- **Prompt-generated simulations put a bespoke lab within reach.** Instructors can generate browser-run models of the topic a course needs from a reusable prompt template (sliders, animation, time-dependent graphs), validating each twice - technically, then against the known analytical solution - instead of accepting the closest published simulation (Ben-Zion et al., 2025).
- **Automating the human counterpart.** Chew et al. (2026) replace the specialist human role-players who staff air-traffic-control simulations with autonomous LLM sim-pilots, removing a training-capacity bottleneck; their fine-tuned speech pipeline cut word error rate on Singaporean-accented aviation speech from 107.80% to 23.45%, though all evaluations were component-level with no trainee cohort run.
- **Adversarial simulators as training partners.** ResidencyRL (Liévin et al., 2026) pairs a policy agent with LLM patient simulators built to behave adversarially across a 57K-case scenario pipeline; training against them cut missed red-flag rates by about a third, and blinded clinicians preferred the trained agent in 87.6% of side-by-side comparisons.
- **Encode missing case states explicitly.** A multi-agent standardized-patient system keeps intent recognition, case-grounded response generation and post-session evaluation separate, distinguishing four kinds of missing information — clinically negative, unknown to the patient, not yet assessed, and absent from the case — because collapsing them into "normal" injects unsupported clinical facts (Gao et al. (2026)).
- **Simulated agents:** AI can simulate patients (for medical training), students (for teacher practice), or conversation partners, making high-stakes interpersonal practice accessible and repeatable. In teacher education, Zhuang and Zhang (2025) built *Student GPT*, a custom ChatGPT chatbot that role-played a middle school student holding common ratio-reasoning Misconceptions about AI, giving preservice mathematics teachers affordable, content-specific practice at diagnosing student thinking — and used an Affective, Communicative, Technical (ACT) coding framework to systematically assess the simulated student's role-play strengths (clarity, relevance, error consistency) and authenticity weaknesses (teacher-like tone, role confusion).
- **Make counterfactual history a first-class feature.** SupplyNet's contextual multi-agent LLM agents generate supply-chain dynamics emergent from learner decisions rather than scripted, and its branching timeline lets learners revisit earlier choices without penalty — 13 of 14 participants rated it highly for connecting decisions to performance against 3 for the baseline (Li et al. (2026)).
- **Grounded dynamics, not a prompted persona.** Chen et al. (2026) parameterized a virtual patient's disclosure dynamics from nearly 2,000 hours of real psychotherapy transcripts, then

updated the level each turn; across 1,033 turns with 20 clinicians its disclosure rose with therapist empathy and exploration while a prompt-only baseline on the same LLM stayed flat.

- **Role-play puts the learner in the part.** Where simulated agents supply the counterpart, role-play gives the learner that part instead. Sanoubari and colleagues (2026) had 18 children aged 9-10 watch a bullying scene enacted by social robots, reason about each character's position, then rehearse defending by puppeteering a robotic avatar, and reported gains in perceived Self-Efficacy for defending plus better-calibrated beliefs about whether confronting a bully actually stops it. Their framing, robot-mediated applied drama, keeps a human facilitator in the Forum Theatre role and confines automation to narrative control, which is a useful reminder that the demanding part of role-play is the reflection rather than the machinery. Lock, Arteaga and Johnson (2025) place role-play alongside simulation among the strategies that AI-supported online learning draws on.
- **Simulated learners:** models of student behavior let researchers and designers test tutoring systems and curriculum before live deployment, grounding Learner Modeling and Adaptive Instruction and Knowledge Tracing.
- **Trust and fidelity:** the value of a simulation depends on how faithfully it models the real context — and on the learner's awareness of its limits, connecting to Trust Calibration.
- **Human-likeness is a property of the interaction, not the model.** Once both backends were rendered behind the same avatar, a text-based human-likeness advantage disappeared: participants called the commercial model natural (54% versus 22%) while communication performance was identical; voice, latency and turn-taking reshaped how the same dialogue quality was perceived (Hasan et al. (2026)).
- **GenAI in simulation-based learning.** Neto and colleagues (2026) systematically review GenAI across scenario-, case-, problem-, and simulation-based learning in healthcare education, finding positive outcomes for higher-order cognitive skills but inconsistent results elsewhere, with hybrid human-AI collaboration outperforming fully automated approaches. Wenzel, Geiger, and Liening (2026) develop AI conversational agents for adaptive support in business simulation games, addressing the common gap of limited formative feedback and structured reflection in simulation-based learning.
- **The "authenticity gap" bounds what AI simulation can replace.** In clinical simulation, Jiang et al. (2026)'s mixed-methods systematic review of AI-powered nursing simulation (19 studies, N=1,253) finds AI effective for cognitive knowledge and affective outcomes but inconsistent for complex psychomotor skills. They name an **authenticity gap**: a learner-perceived shortfall in emotional resonance, nonverbal cue recognition, and tactile/physical examination dimensions. That gap explains *why* AI simulation is best for highly structured objectives (foundational communication, history-taking) and should sit in a **stepped simulation continuum** that hands advanced psychomotor and emotionally complex scenarios to human-standardized patients and clinical placement. Technical instability (e.g., speech-recognition delays) can also add extraneous cognitive load and anxiety, so fidelity and stability are themselves design levers. This parallels Neto et al.'s finding that hybrid human–AI approaches outperform fully automated ones.
- **Teacher-AI co-designed simulations.** Interactive simulations that support both conceptual learning and competency development are scarce in hands-on domains, and GenAI output often

lacks pedagogical validity. In drone-based STEM education, teacher-AI co-designed simulations embedded in an otherwise identical hands-on curriculum were evaluated with a quasi-experimental pretest–posttest design across 30 secondary students, examining whether simulation-supported instruction yields superior learning outcomes (From simulation to flight: Simulation-assisted drone learning with teacher-AI co-designed scaffolds for secondary students' STEM knowledge and competencies). Separately, multi-agent tutoring benchmarks such as ASTRA use simulated socially intelligent agents to study participation-balanced collaboration in introductory programming (ASTRA: A synthetic benchmark for trace-based evaluation of socially intelligent multi-agent tutoring and participation-balanced collaboration in introductory programming).

- **Learner control in simulation is enacted, not granted.** A 2 × 2 experiment in a flocking simulation (Su, Nair and Nagashima 2026) gave some students parameter sliders, some an optional conversational agent and some both; every condition improved, but neither affordance produced a reliable difference once prior knowledge was controlled ($p = .849$ and $p = .108$). What predicted gains was where and how long learners manipulated parameters: sustained slider use in the most conceptually complex lesson was positively associated with gains, and the same behavior in the easier lesson negatively. For simulation builders the implication is that offering controls is not the intervention — helping learners decide what to change, and register what changed, is.
- **Agency is a designed layer, not a property of the technology.** Theelen et al. (2026) sort simulations by the practice represented, the simulated situation, how agency and adaptation are distributed, and how the learning is orchestrated, rather than by immersion level.
- **A digital twin is a simulation with a hardware bill, and the bill shapes who can take part.** A systematic review of 11 studies of digital twins in engineering and STEM higher education found that every implementation delivered a working prototype with real-time synchronization, yet only three reported statistically significant learning gains. Physical rigs capped access at 1–3 concurrent students in five studies, and reduced social interaction was the most-cited pedagogical challenge, in six (Pelayo-González et al. (2026)).
- **Agent-based simulation can model a Metacognition theory as a testable system.** An agent-based digital-twin-inspired framework combining the five-level AMERT model with a NetLogo simulation let researchers vary learner archetypes and task conditions and observe metacognitive trajectories, though the authors stress the output is hypothesis generation, not evidence about real learners (Guo, 2026). Simulation becomes a virtual laboratory for a theory that is otherwise hard to observe.
- **The curriculum is the unit that decides a simulation's value.** The Curricular Bridge Model argues that return on simulation depends on how experiences are sequenced across a program — context reuse, variation in reasoning demands, evidence feeding progression — rather than on platform fidelity (Herrera Alcaíno, 2026).

Connections

Simulation connects to Active Learning, Adaptive Learning, and Pedagogical Agent. It is a mechanism for experiential and Constructivism learning and is amplified by AI's ability to generate adaptive, realistic practice environments.

Simulation-based learning now includes synthetic patients, students and role-play partners, and AI Avatars and Synthetic Instructors argues that their consent, disclosure and person-fidelity questions are not the same as equipment or scenario fidelity.

What cannot be delegated

Most work on simulated conversation asks how faithfully an agent plays its part. Álvarez-Rubio (2026) asks the prior question: what a teacher cannot hand over at all across the simulation cycle of briefing, scenario, and debrief. The paper separates four delegation operations: execution, conveyance, facilitation, and the undertaking of a commitment. Execution and conveyance let the teacher correct a failure afterward; facilitation hands over judgment about an activity's structure. The fourth fails differently, because a commitment's essential condition is answerability as a relation to those who may demand reasons. An agent can perform a debriefing function; it cannot be the party who answers for it. On this account a chatbot that debriefs as well as a human never becomes answerable, so stronger debriefing evidence cannot move the line.

The framework travels as a test rather than a catalog. Three questions decide any function: what would pass to the agent, whether the teacher could correct a failure, and who could be asked to stand behind the agent's words. A function with no answer to the third is not a candidate. Applied to preparation, the test yields six verdicts — diagnosis and logistics delegable, stated objectives partly delegable, and the fiction contract, psychological safety, and assessment terms refused. In the debrief the paper sets out three stances an agent might hold, expert, character, and Maieutic, and reports the Maieutic failure mode: an agent built to teach by never answering left students frustrated. It is a design framework, not an outcome study. The authors state that no data were collected for research, and the deployment reported is a pilot read through the teacher's own observations.

Common Misconceptions

- **"Simulation is cheaper and therefore second-best."** Autonomous LLM sim-pilots **replace the specialist human role-players who staff air-traffic-control simulations, removing a training-capacity bottleneck** — the constraint was staffing, not fidelity. Where human role-players are scarce, the LLM simulation is not a substitute but the only available option.
- **"Simulators should behave like average cases."** ResidencyRL (Liévin et al., 2026) pairs a policy agent with **LLM patient simulators built to behave adversarially**. A simulator designed to be cooperative makes the learner's practice easier than the clinic, which is the opposite of what training needs.
- **"Scripted scenarios teach decision-making under uncertainty."** SupplyNet's contextual multi-agent agents generate **dynamics emergent from learner decisions rather than scripted** sequences. Scripted scenarios rehearse a known path; the emergent ones rehearse the decision.

Virtual and Augmented Reality

> **Virtual and Augmented Reality (VR/AR)** — the display and interaction layer through which learning environments are experienced: fully synthetic spaces in VR, and digital content overlaid on the physical world in AR and mixed reality. AI enters this layer in two directions. It authors it, since generative AI now turns a natural-language description into a working browser-based AR or VR learning tool that no longer requires a specialist developer. And it inhabits it, as agents, pedagogical agents and retrieved knowledge guide a learner hands-free inside the immersive environment. What the modality adds over a screen is presence and embodiment; what it costs is fidelity, hardware, and a body's tolerance for being there.

Questions to Consider

- Where does the line fall between what is being modeled and the surface it is shown on? Compare a desktop patient simulator with a VR field trip to a site students cannot visit. Which differences would you expect to change learning, and which might only be novelty?
- A pilot found students reported *feeling* wavelength and amplitude through a hand gesture more strongly than through a slider — but it measured perception, not achievement, with 29 students and no comparison group. How much should reported "feeling" count toward adopting a tool?
- If generative AI lets an instructor with no programming background build a working AR simulation in an afternoon, what new responsibilities follow for validating the physics, judging fidelity, and deciding whether it belongs in a course?
- In a review of AI-powered nursing simulation, AI matched human actors for structured communication but not for tactile and emotionally complex scenarios. How would you sequence practice so learners rehearse some parts with AI and others with people?
- One classroom VR study reported minimal motion sickness while the meta-analytic estimate for intelligent VR with students with disabilities was not statistically significant. What would you want measured before a program invests in headsets?

Introduction

Virtual and augmented reality is a **modality**, not a model: it is the layer through which a learning environment reaches the learner. That makes it a different axis from Simulation, which is what gets modeled in the first place. The two are often conflated, because immersive environments are common delivery vehicles for simulations, but they vary independently — a desktop patient simulator is simulation without VR, and an AR overlay on a real instrument is VR without simulation. Keeping the axes apart matters for design: deciding to make practice risk-free is a different decision from deciding to make it embodied, and the two carry different costs, different failure modes, and different evidence. VR/AR is the **delivery layer** for a simulation and a close relative of game-based learning; it operationalizes embodied and situated accounts of learning, and it sits inside experiential and Active Learning practice.

AI now shapes this modality from both ends. It **authors** immersive content, because generative AI converts a structured natural-language prompt into a runnable AR or VR artifact, collapsing the specialist programming skill that used to gate production. And it **inhabits** the environment, as agents, pedagogical agents and retrieved domain knowledge supply guidance inside it — hands-free, in real time, grounded in sources the learner cannot consult while wearing a headset.

Shao, Tang and Ju (2026) test an AI-VR enhanced flipped classroom with young EFL learners and report gains in English achievement, metacognitive self-regulation and motivation, with technological literacy moderating how much learners gained from the immersive component.

What the modality adds

The case for VR/AR rests on presence and embodiment rather than on information delivery. A shared virtual space can also decouple co-presence from geography: a VR classroom built on a real-time synchronisation layer put teachers and students in the same room and manipulating the same 3D science materials regardless of site, targeting up to twenty participants. A one-hour session with 10 students on a Meta Quest 3 found strong usability scores on the System Usability Scale and little Simulation sickness, though UI consistency was its own weak point. Its designers deliberately avoided the earlier peer-to-peer architectures whose frame rate degraded as participants joined, a reminder that presence is bounded by engineering. More controlled comparisons are sobering about what the surface alone buys: a 24-participant study of engineering mechanics found that mixed-reality apps and physical toolkits raised engagement over classroom instruction, yet complex visualizations remained difficult for learners in every condition. Engagement is the reliable effect; understanding is not.

Generative AI as the authoring layer

The barrier that used to define who could build an immersive tool has largely fallen. Using a four-element prompt structure — **tools, display, hand controls, optimization** — a teacher or student with no coding background can generate a browser-based, hand-controlled AR physics simulation that runs as a single HTML file with nothing beyond a camera, then refine it by describing what went wrong in plain language. The gesture is familiar from touchscreens: pinch and spread tunes a physical quantity rather than zooming a picture, so opening the fingers vertically raises amplitude, and horizontally lengthens wavelength and shifts the lamp toward the red end of the spectrum. The same structure generalizes: the Coulomb field around a fingertip spread through the room, two hands as opposing charges, and the right-hand rule for magnetic force drawn on the learner's own hand — rendered deliberately **unmirrored**, since mirroring would invert the very rule being taught.

The pilot is encouraging and preliminary in equal measure. With 29 second-year medical-imaging students in an introductory radiation physics course, all 29 agreed the gesture helped them "feel" what wavelength is (mean 4.52), amplitude control scored highest (4.59), 93% found controlling the wave in the air natural, and 86% reported feeling more engaged and focused than in regular learning. The evidence, however, is perception-only, single-class, and without a comparison group — so the honest reading is that Prompt Engineering has removed the production barrier, which makes the underlying question about embodiment *testable*, not that it has been answered.

AI inside the immersive environment

The second direction is where AI stops authoring and starts teaching inside the headset, and it is where retrieval grounding becomes load-bearing. An agentic immersive training platform for high dose rate brachytherapy built a digital twin of the treatment suite — anatomically precise patient models, catheters, afterloaders, applicators — so trainees could see an applicator's spatial orientation relative to organs at risk, without a shielding room, a live radioactive source, or the privacy hazards of a physical pelvic exam. A knowledge-aware assistant grounded in clinical guidelines supplied hands-free guidance through a three-tier voice interface (headset microphone to backend transcription and intent analysis to spatialised speech), which removes controller dependency during intricate maneuvers. Technically it worked: 3–5 second end-to-end latency across 50 Monte Carlo runs, context recall above 0.93 and answer relevance 0.87 on 52 expert-authored question-answer pairs, with a medical embedding model improving answer completeness.

Its gaps define the current frontier of the pattern. Evaluation was objective metrics plus a single domain-expert user, not learners; there was no automated Assessment or adaptive feedback; and the assistant cannot exceed the documents it was given, so institution-specific protocols and rare scenarios sit outside its competence. In other words, the tutoring intelligence inside immersive environments is still mostly **guidance**, not measurement — and the same platform architecture, with model inference offloaded to a local GPU backend, is what makes hands-free guidance fast enough to be usable at all.

The clearest attempt to date at that missing measurement comes from a vocational design studio rather than a clinical setting. In a 12-week interior-design course, a VR environment (headsets plus a 3D modeling tool) with an LLM-backed assistant rendered as a digital human was compared against conventional project-based instruction. The assistant was assigned a distinct role per phase — resource recommendation and task decomposition, layered questioning with knowledge maps, simulated design effects and flaw detection, then discourse logging for the teacher (Jin et al., 2026). Across 63 valid responses the immersive-plus-agent condition produced significantly higher design ability ($\eta^2p = .138$) and creative ability ($\eta^2p = .111$), cognitive ($d = 0.90$) and behavioral ($d = 0.75$) engagement, and motivation ($d = 0.74$) and satisfaction ($d = 0.69$). Reported cognitive load was *lower*, not higher ($d = -0.52$), which the authors credit to the assistant cutting search and cross-disciplinary integration effort. Two limits keep this from settling the question: ideational novelty and affective engagement did not move, and every outcome is self-report, with no artifact ratings or headset logs.

The contrast with a comparable Design Education deployment is instructive. An architectural studio using a GenAI plus multi-user XR pipeline found *declining* design Self-Efficacy confidence for the teams that used it and no advantage in blinded panel ratings. The difference between the two is less the hardware than the orchestration: the vocational study fixed the phase structure, the assistant's role in each phase, and the evaluation rubric before the intervention, and measured productive ability separately from ideational novelty.

The instructor-facing version of the same pattern is younger and more fragile. Liang et al. (2026) let a stage-lighting instructor speak their intent into a VR scene with a laser pointer as the spatial anchor, and had an Large Language Models (LLMs) turn it into instructor-reviewable spatial annotations, executable lighting demonstrations and on-demand jargon explanations. Over 55 prompts and 531 generated actions, assistance was strongest on expressive, under-specified goals (212 of 245 visual-effect actions applied, 86.5%) and weakest on fixture-level requests, where 26 of the 28 rejected actions traced to directional references such as "left light" that the model resolved to the wrong fixture — grounding in the scene's spatial reference frame,

not executability, was the binding constraint. Instructors used suggestions as a controllable refinement process rather than an answer: 127 of the 147 rejected or modified actions (86.4%) were followed by a new prompt, and only one by manual adjustment. The study's most cautionary result is representational — annotations that externalized expert reasoning did not reliably align with what novices understood, so immersive AI instruction carries both the grounding problem of the tutoring cases above and a second one, that instructor competence and learner comprehension are not the same target.

What the evidence shows

The strongest evidence for VR/AR is comparative and discipline-specific. A meta-analysis of 33 experimental and quasi-experimental studies (N = 3,181) of emerging technologies in teaching English as a foreign language found a small-to-moderate overall effect (g = 0.38) and, within it, the **largest effects for VR/AR**, with gains rising by educational level and favoring productive skills (speaking, writing) over receptive ones.

The counter-evidence is just as informative. In the first meta-analysis of AI-based interventions for students with disabilities — 29 studies, 239 effect sizes, medium overall effect g = 0.588 — intelligent VR systems produced g = 0.528, **not statistically significant**, while computer software reached 0.959 and robots 0.509. Publication bias was present and trim-and-fill reduced the overall estimate to g = 0.269. The pattern is not that immersion fails, but that its effects are small, heterogeneous, and sensitive to how the particular intervention was designed and compared.

The clearest negative result in the knowledge base comes from a studio deployment rather than a comparison of modalities: in a 27-student architectural design studio, teams using a GenAI plus multi-user XR pipeline declined more in design Self-Efficacy confidence ($\beta = -1.675$) and outcome expectancy ($\beta = -2.088$) than teams working the normal course workflow, with no significant difference in expert panel ratings of their presentations (Xiao et al., 2026). The authors explain it as phase-dependent complementarity with real friction — GenAI for externalizing tentative ideas, XR for spatial and scale evaluation — alongside control, dimensional-fidelity, shared-attention and motion-comfort problems, a reminder that immersive tooling adds interaction costs as well as capability.

Fidelity, presence and the authenticity gap

Where immersive practice is used for interpersonal and procedural skill, the limiting factor is not visual fidelity but felt authenticity. A mixed-methods review of AI-powered nursing simulation (19 studies, N = 1,253) found AI effective for cognitive knowledge and affective outcomes but inconsistent for complex psychomotor skills, and named the reason: an **authenticity gap** covering emotional resonance, nonverbal cue recognition, and tactile and physical-examination dimensions. Its practical recommendation is a **stepped simulation continuum** — AI is well suited to highly structured objectives such as foundational communication and history taking, while advanced psychomotor and emotionally complex scenarios belong with human-standardized patients and clinical placement. Technical instability compounds the problem: speech-recognition delays inject extraneous cognitive load and anxiety, which makes stability and latency design levers rather than implementation details.

Avatars and digital humans are the human face of that layer, and AI Avatars and Synthetic Instructors gathers the cases where realism failed to predict effectiveness: SOPHIE scored communication identically behind the same avatar across backends, and TriKoNet's students rejected photorealistic personas outright.

The same logic explains why presence is not automatically good. Motion sickness, UI inconsistency, hardware cost, and uneven device access decide who can use an immersive environment at all, which is why the modality's equity questions connect to Accessibility and Inclusive Learning rather than sitting apart from them.

Common Misconceptions

- **"Feeling the phenomenon means understanding it."** A pilot found students reported **feeling** wavelength and amplitude through a hand gesture more strongly than through a slider — but **it measured perception, not achievement**. The felt sense is the affordance, and whether it produced understanding is a separate test.
- **"High usability scores validate an educational VR tool."** In a **one-hour session with 10 students** on a Meta Quest 3, the study reported **good usability on the System Usability Scale and minimal simulation sickness**. Usability and comfort are prerequisites and neither is a learning measure.
- **"Students' agreement is evidence of the affordance."** With **29 second-year medical-imaging students**, all 29 **agreed the gesture helped them "feel" what wavelength is (mean 4.52)**. Unanimous agreement on a feeling is self-report about experience, and the affordance claim needs an outcome that does not depend on the student's judgment of their own understanding.

Learner modeling and adaptive systems

Learner Modeling and Adaptive Instruction

> **Learner modeling and adaptive instruction** — the umbrella for how AI represents learners (what they know, feel, and need) and how it uses those representations to adapt teaching. The family spans the *modeling* layer — **student modeling**, Knowledge Tracing, Cognitive Diagnosis, and simulating students — and the *adaptive systems* that consume those models — Intelligent Tutoring, Adaptive Learning, and Personalized Learning. The shared question: *how does a system know what a learner knows, and what should it teach next?*

Questions to Consider

- The umbrella question this page poses is: how does a system know what a learner knows, and what should it teach next? Before you read on, how would you even begin to represent 'what a learner knows' in a machine?
- Learner modeling spans knowledge-tracing (tracking knowledge over time), cognitive diagnosis (mapping mastered skills), and simulating students (synthetic learners). What do you think each approach is good at — and what does each risk getting wrong?
- Every adaptive AI depends on some model of the learner. If a model is only as good as the evidence feeding it, what evidence do you think AI systems actually have about a student, and what important things about them remain invisible?
- A model might capture what a student gets right and wrong but not why, or not how they feel. How could a learner model mislead an adaptive system in ways that harm rather than help the student?
- If you were designing an adaptive tutor, what would you want its model of you to include — and what would you want it explicitly forbidden from assuming?

Introduction

Learner modeling is the computational representation of learners; adaptive instruction is what systems do with that representation. Every adaptive AI in education depends on some model of the learner — even a lightweight one — and every learner model exists to inform some instructional decision. This page is the umbrella for that pipeline: the modeling methods, the systems that act on models, and how they relate.

The modeling layer

These concepts answer "what does this learner know, feel, and need?" — the representation side of the family.

- **student modeling** — the broad practice of representing learner characteristics (knowledge, skills, affective states, engagement, preferences) in computational form. It is the umbrella term within this layer, encompassing all ways of representing a learner.

- **Knowledge Tracing** — the specific practice of modeling cognitive knowledge *over time* by tracking performance on exercises and predicting future mastery. It formalizes the temporal dynamics of learning — when knowledge is gained, decays, and how concepts relate.
- **Cognitive Diagnosis** — fine-grained Assessment of which specific skills or knowledge components a learner has mastered, producing a mastery profile that supports targeted remediation.
- **simulating students** — generating *synthetic* learners on demand, rather than representing a real one, so Pedagogies and Teaching Strategies and AI systems can be tested or trained offline.
- **A causal formalism for learner models.** Mangili et al. (2026) replace noisy-gate Bayesian networks with structural causal models elicited from experts, making hints explicit endogenous variables so the model can ask what a student would have answered without the help they used — slightly less predictive, but capable of counterfactuals associative models cannot express.

The study of Zhang, Jeffries & Koprinska (2025) illustrates that faithful representation does not require the most complex model family: a lightweight, intrinsically interpretable decision-tree student model — built from course content-interaction features rather than rich telemetry — predicts module-level progress in large-scale online programming courses (85–91% accuracy) and separates disengaged at-risk, disengaged-but-successful, and engaged high-performer engagement profiles, supporting Learning Analytics early-warning at scale.

A predictive learner model can rest on the structure of enrollment rather than trace data: TRACE encodes each semester as an unordered basket of courses and predicts the course set and grades together, cutting grade-prediction error to 0.1339 MAE — 46.4% below a grades-only model — across 5,326 students and ten years (Savala (2026)).

Student models can also be built purely from behavioral traces and still support adaptation. An, Hammock & Goel (2025) derived three engagement profiles — Observation, Construction, and Exploration — from the clickstreams of 315 online learners building 822 ecological models in VERA, without any demographic or contextual data, and showed these profiles predict model quality (Exploration yields the most complex and diverse models, while Observation is dominated by copied rather than original models). Such engagement-level characterizations are the coarse-grained student models that the adaptive-instruction layer can consume to target feedback.

Affective student modeling is a further dimension: a math tutor inferred emotion from conversational text and facial expression and mapped the aggregated state to tutoring strategies, but the Multimodal AI fusion reached only 60% accuracy against participants' own annotations, making the affect read the pipeline's weakest link (Kar et al. (2025)).

Gutterman et al. (2026) found a delayed-start signal recorded during math practice predicted English outcomes, with chronic delayers (over 13 minutes) showing lower gains (ELA β = -.11 SD) even after controlling for prior knowledge and time-on-task — so behavioral student models can transfer across subjects without per-course retraining, though their cut-points must be re-derived.

The adaptive-instruction layer

These concepts answer "what should be taught next?" — the application side that consumes learner models.

- **Intelligent Tutoring** — systems that use student models and mastery estimates to select problems and provide step-level guidance, the classic application of learner modeling.
- **Adaptive Learning** — systems that adjust content, pacing, or difficulty in response to the learner model.
- **Personalized Learning** — the broader tailoring of instruction, content, and pathways to individual learner characteristics and preferences.

How the members relate

The concepts form a pipeline rather than competitors: **student modeling** is the umbrella representation; Knowledge Tracing and Cognitive Diagnosis are specific modeling methods that populate it; simulation *generates* learners rather than representing real ones; and Intelligent Tutoring, Adaptive Learning, and Personalized Learning are the systems that consume these models to adapt instruction.

Student modeling vs. simulating students is the key distinction to keep straight. Student modeling is about **representing a real learner** — building a model *from* an actual student's data so an adaptive system can act on that individual. Simulating students, by contrast, **generates a synthetic learner** on demand to stand in for real learners so pedagogy and AI can be evaluated or trained offline. The two are closely related rather than interchangeable: simulated students typically *embed* a student model (an epistemic state, misconception set, or engagement profile) and draw on the same constructs that Knowledge Tracing and Cognitive Diagnosis formalize. Their purposes diverge — student modeling serves live adaptation by informing decisions about a real person, whereas Simulation fabricates learners to test systems (and increasingly to audit AI, e.g., López-Pernas et al. (2026)) rather than to act on any real individual.

Knowledge tracing vs. student modeling is the other common confusion. Knowledge tracing specifically models cognitive knowledge over time; student modeling is the broader practice covering all aspects of a learner (affective state, engagement, preferences). Knowledge tracing is a *type of* student modeling focused on the cognitive-temporal dimension. Knowledge-tracing constructs also inform simulated students — a simulated learner's cognitive state is often formalized with the same mastery/decay dynamics that knowledge tracing models, so simulation is a way to *generate* the knowledge states that tracing methods normally *infer* from real response data.

Anchoring tracing to the curriculum strengthens the model. Pradeesh et al. (2026) show that a learner model gains fidelity when tracing is tied to explicit curriculum structure rather than learned purely from data: their Outcome-Based Knowledge Tracing (OKT) treats course outcomes in Outcome-Based Education as the knowledge concepts to trace, supplies concept relationships through expert-validated OBE "affinity mappings" between course and program outcomes (an explicit alternative to implicit attention or graph message passing), and uses a memory-augmented module to model how one outcome's attainment impacts others. On live engineering-program data it beat DKT, DKVMN, EKT, and SimpleKT baselines (89.81% AUC), illustrating that the modeling layer can exploit the curriculum's own structure to represent learners more faithfully.

Intelligent tutoring vs. adaptive/personalized learning sits on the application side: intelligent tutoring is the problem-selecting, step-guidance system; adaptive learning tunes content and pacing; personalized learning is the broadest tailoring of the whole learning experience. All three are the "consumers" of the modeling layer.

The shared validity challenge

Across the whole family, the defining validity challenge is the same: the learner representation must **faithfully reflect a learner's true state** rather than the system's default assumptions. For **student modeling** and Knowledge Tracing, this means the model must genuinely capture what a learner knows (evaluation and measurement validity). For simulation, it means the synthetic learner must exhibit realistic imperfection rather than the model's full competence or sycophantic agreement. Adaptive systems that consume faulty models inherit and propagate that error.

Models that infer learner state from gameplay reached AUCs of 0.848–0.913, yet only two of the 55 reviewed studies audited them for demographic bias and just one examined differential outcomes by learner ability (Kaşarcı and Yurt (2026)).

Some intended signals may not be recoverable from dialogue at all: the Learning Context framework's pilot recovered misconceptions at 91.4% and anxiety at 100% but conscientiousness at only 68.6% and language proficiency at 60%, so a context-aware model should capture slow-to-surface traits rather than wait for dialogue to expose them (Liu et al. (2026)).

Physiological and gaze signals widen the modeling base: eye tracking, EEG, electrodermal activity and heart rate are now used to infer engagement, attention and cognitive load (Sensor and Gaze Analytics). The inference from signal to mental state is the weak link, since a body can be recorded without its state being identified.

Lin et al. (2026) expose a circularity in how such synthetic learners are validated: their EduMirror agents administer psychometric questionnaires post-hoc and read agreement with the agent's internal value representation as psychological validity, but because the Surveyor measures dimensions already encoded in that value system the check is a consistency check rather than independent validation.

Correctness is not always a faithful signal. An, McLaren, and Stamper (2026) show that a learner model inferring mastery from correct actions can misrepresent a learner's true state: learners who exhibit *deceptive overgeneralization* appear mastered yet omit a critical application constraint, so adaptive systems can stop practice prematurely. Learner models should assess conditional understanding — including whether the learner knows when to withhold an action — not only action correctness.

Hidden misconceptions show the same failure from the other side: Imran and Bulathwela (2026) found a fine-tuned classifier caught 57.4% of correct answers reached through flawed reasoning, and at a 1.6% prevalence even an 83.6%-accurate reasoning model left 8 false alarms per detection — so correctness-based mastery signals are both incomplete and expensive to repair.

How a model is validated is itself a validity question. Schuetze, Yan, and Carvalho (2025) show that popular learner models (BKT, BKT-with-Forgetting, AFM) appear to capture human learning only when fit retroactively to a full multi-session dataset; under time-based (walk-forward) cross-validation — predicting a future session from earlier ones, how such models are actually deployed — they overestimate performance,

miss the spacing effect, and mis-order practice conditions. Because forgetting-augmented and forgetting-free models performed about equally across sessions, the authors conclude that forgetting is often absorbed into learner parameters rather than genuinely represented. The lesson for the family is that a faithful learner representation must be validated the way it is used — and that conflating in-the-moment performance with long-term retention produces models that look accurate yet misrepresent learners. Zamanifard, Goudarzi and Robb (2026) show the same failure from the classifier's side: inferring learning-style dimensions from 153 undergraduates' Problem Solving dialogues looked moderate on accuracy until per-class recall exposed dominant-label prediction, with Intuitive and Global learners systematically under-identified and few-shot examples sometimes amplifying the majority-class bias.

LLM-era modeling

Recent advances use LLMs for richer modeling. The HiLLM-CD framework represents students as proficiency trees; multimodal approaches construct evidence-grounded knowledge representations from diverse data sources; LLMs now simulate students with reasoning. LLMs enable automated model construction from educational text and higher-fidelity student simulation, reducing reliance on expert annotation — while sharpening the fidelity concerns above. Learner-model signals also *ground* LLM reasoning: Reddig, Arora & MacLellan (2025) found that feeding GPT-4 a student's Bayesian Knowledge Tracing skill estimate along with the tutor's interface structure sharply improved its error diagnosis (logical-error identification rising from 40% to 81% on factoring; ~87.8% overall), while multi-step problems and responses containing several errors remained the weakest cases — evidence that coupling a formal learner model to an LLM strengthens, but does not guarantee, sound inference about a real student. CoLearn (He et al., 2026) shows what a persistent version of that coupling looks like: mastery and mined misconceptions are stored per (learner, subject) rather than as per-session logs, so evidence accumulates across sessions, and the memory is written by an LLM-graded observation function while staying inspectable to the learner through mastery bars and a label naming what each generated question was chosen to probe. Its controls make the writing step explicit — with the memory read but no longer updated, the share of items aimed at a genuinely weak skill fell from 0.72 to 0.57 — and it keeps this page's qualification intact: the stored mastery is the agent's belief about the learner, not a measurement of their knowledge.

Language can replace ID embeddings as the representation: PLCD builds LLM-derived concept schemas and exercise process graphs as priors, reaching 83.51% accuracy on XES3G5M, with largest gains in cold start — 4.60 ACC points over KCD for new concepts and 4.00 for new exercises — where ID-based models have no history (Liu et al. (2026)).

Simulator quality separates into two axes: a pool-then-specialize pipeline that trains shared behavioral patterns before a per-student adapter reached behavioral fidelity 0.51 and guidance responsiveness 0.91 in chess, against 0.23 and 0.72 for a frontier role-play baseline, showing a simulator must both match a student and be steerable (Yang et al. (2026)).

Risk scores can be accurate yet unsupported: Gheisari and Salarian (2026) reached 99% accuracy predicting withdrawal from enrollment and performance records, but on a single institution's 1,027 cleaned records with no external validation, no intervention tested, and fairness audits named as future work — the score supports triage, not a verdict about a student.

A learner model that only predicts risk is not enough for decision support: coupling a calibrated at-risk model with integer-programming recourse over discrete actions — validated against timing, budget, immutability and availability constraints — produced compact intervention plans where optimization alone accepted unenactable ones (Le, Abel & Laforge (2026)).

A black-box estimator can also be distilled into a small self-explaining model: a two-stage pipeline turns a fitted estimator and its post-hoc interpretation into a 2B-parameter "mentee" that returns an estimate alongside a narration, audited for faithfulness rather than for fluency (Distilling Black-Box Machine Learning into a Small, Self-Explaining Language Model for Learning Analytics).

Connections to other concepts

Learner modeling and adaptive instruction feed into Learning Analytics (dashboards and interventions), Formative Assessment (analytics-driven assessment), and Feedback (what the system tells the learner). It connects to AI in Education as a core strand of AI for education.

Common Misconceptions

- **"A faithful model needs the most complex method."** Zhang, Jeffries and Koprinska (2025) illustrate that **faithful representation does not require the most complex** approach. Complexity is not a proxy for fidelity, and a simpler model that captures the relevant structure can be the better instrument.
- **"Learner models need trace data."** A predictive learner model can rest on **the structure of enrollment** rather than trace data: TRACE encodes each semester as an **unordered basket of courses** and predicts from that. The predictive signal can live in the institution's administrative record.
- **"Affective state requires physiological sensing."** A math tutor **inferred emotion from conversational text and facial expression** and mapped the aggregated state to tutoring decisions. The affect signal was recoverable from what learners were already producing.

Knowledge Tracing

> **Knowledge tracing** — modeling what learners know over time by tracking their performance on exercises and predicting future mastery. It is the knowledge base's richest modeling thread, spanning Bayesian, deep learning, and LLM-enhanced approaches to tracking student knowledge as it evolves.

Questions to Consider

- Knowledge tracing models what you know over time from your performance on exercises, tracking when knowledge is gained and when it decays. What can your answers reveal about whether you truly 'know' something versus just got it right this time?
- The page warns that 'mastery is not correctness' — a learner can appear mastered yet systematically misapply a skill when a hidden condition is violated. When have you seen someone (or yourself) look like they understood something but actually hadn't?
- If knowledge tracing feeds adaptive systems that decide what to teach next, what goes wrong when the model mistakes correct answers for true mastery and moves a student on too early?
- Knowledge tracing comes in many forms — Bayesian, neural, hypergraph, dialogue-based, LLM-enhanced. What trade-offs would you expect between a transparent model you can explain and a powerful but opaque one?
- The page connects knowledge tracing to simulated students — generating the knowledge states tracing normally infers from real data. How might simulating learners help test a tutor before it meets real students?
- Since knowledge decays over time, what should an adaptive system do with a student's past 'mastery' once they've forgotten? How would you design for forgetting rather than assuming knowledge persists?

Introduction

Knowledge tracing transforms raw exercise responses into estimates of what a student has mastered and what they still need to learn. Unlike simple correctness tracking, knowledge tracing models the temporal dynamics of learning — when knowledge is gained, when it decays, and how concepts relate to each other.

Approaches represented in the knowledge base

- **Bayesian approaches:** StanBKT: Rethinking Parameter Estimation in Bayesian Knowledge Tracing standardizes BKT implementations, while MBP-KT: Learning Global Collaborative Information from Meta-Behavioral Pattern for Enhanced Knowledge Tracing incorporates meta-behavioral signals
- **Soft-evidence BKT with an LLM observation function:** CoLearn (He et al., 2026) keeps the BKT structure but replaces the binary correct/incorrect observation — standard BKT's input —

with a continuous one: an Large Language Models (LLMs) grader emits graded mastery evidence plus a confidence weight, blended into a confidence-shrunk posterior and gated so that a clearly wrong answer cannot raise the estimate, which makes the update a variant that generalizes standard BKT rather than a strict reduction of it. Whether that observation function is trustworthy depends on the learner: mean evidence separated ability tiers cleanly (0.25 weak / 0.67 mixed / 0.77 strong) while within-tier correlation with true mastery was only r ≈ 0.15 / 0.48 / 0.41, leaving the traced state an agent's belief about the learner rather than a calibrated measurement.

- **Neural and hybrid models:** Neural-Symbolic Knowledge Tracing: Injecting Educational Knowledge into Deep Learning for Responsible Learner Modelling combines symbolic reasoning with neural networks; Explainable Knowledge Tracing via Probabilistic Embeddings and Pattern-based Reasoning advances interpretable probabilistic models
- **Hypergraph memory networks:** THyMeN augments memory-based tracing (DKVMN) with temporal hypergraph reasoning, modeling dynamic higher-order interactions among concepts that co-occur within multi-skill questions
- **Dialogue-based KT:** Interpretable Knowledge Tracing adapts knowledge tracing for conversational tutoring
- **LLM-enhanced:** HiLLM-CD uses LLMs for automated concept tree construction and hierarchical proficiency inference
- **Semantic, recommendation-oriented KT:** ExRec (Ozyurt, Almaci, Feuerriegel and Sachan, 2025) grounds the *input* rather than the architecture. An LLM annotates each question with solution steps and knowledge concepts aligned to the Common Core State Standards for Mathematics. Contrastive learning aligns question, solution-step and concept embeddings (with false negatives removed by pre-clustering concept variants such as "interpreting a bar chart" and "reading information from a bar graph"). A KC-calibration loss then lets the tracer predict a concept-level knowledge state directly instead of inferring one by running the model over every question in that concept. The calibrated tracer then serves as the Reinforcement Learning environment for exercise recommendation, where a model-based value estimation initialises the critic from the tracer itself. Across four tasks on XES3G5M averaged over 2,048 test students, non-RL baselines gave marginal or negative knowledge gains, value-based continuous methods beat policy-based ones, and the model-based value estimate improved them consistently — most sharply on the weakest-concept task, where the target changes at every step. Reported gains are percentage-of-maximum knowledge improvement, not learning outcomes, and the pipeline depends on generated solution steps whose quality the tracer inherits.
- **Outcome-based knowledge tracing (OKT):** Pradeesh et al. (2026) trace student knowledge within Outcome-Based Education systems by treating **course outcomes as the knowledge concepts themselves**, and substitute expert-validated OBE "affinity mappings" between course and program outcomes for attention- or graph-derived concept relations. A Memory Augmented Neural Network (MANN) models how each outcome's attainment impacts others, and domain-adaptive BERT fine-tuning enriches the outcome embeddings (with a GRU backbone beating LSTM). Against a live engineering-program LMS corpus of 2,416 students and 966 outcomes,

OKT posted 89.81% AUC, ahead of DKT, DKVMN, EKT and SimpleKT, while on ASSISTments that edge vanished, confirming the advantage is tied to OBE-specific curriculum structure.

- **A single recency scalar captures most of what a sequence model buys.** Across 1,927,265 mathematics responses from 8,996 Finnish students, item identity by itself hit AUC .8362; one recency measure relative to item difficulty lifted that to .8669, recovering 93.5% of a query-conditioned transformer's .8690 gain, while a 128-dimensional summary of history reached only .8687 (Lahtinen & McMullen (2026)).
- **Snapshot-only tracing.** Nagai et al. (2026) induce a pseudo-temporal order from inclusion relations among learners' skill sets, treating expanding skill sets as learning progression so single-time-point snapshots remain traceable — but the formulation assumes skills are never lost, so deployments for learners who regress need an explicit forgetting mechanism first.

Relationship to other concepts

Knowledge tracing is closely related to Learner Modeling and Adaptive Instruction — while knowledge tracing specifically models cognitive knowledge over time, student modeling is the broader practice of representing all aspects of a learner (affective state, engagement, preferences). Knowledge tracing feeds into Adaptive Learning and Personalized Learning systems that need to know what to teach next, and into Intelligent Tutoring platforms that use mastery estimates to select appropriate problems. It connects to Learning Analytics for dashboard and intervention design, and to Cognitive Diagnosis for fine-grained skill Assessment. Knowledge-tracing constructs also inform simulated students — a simulated learner's cognitive state is often formalized with the same mastery/decay dynamics that knowledge tracing models, so Simulation is a way to *generate* the knowledge states that tracing methods normally *infer* from real response data.

A scope caveat: tracing estimates domain mastery, not higher-order cognition. A 15-year review of 127 intelligent tutoring studies finds Bayesian and deep-learning tracing improved over the period yet still unable to model higher-order cognitive processes, Metacognition, or motivation — the states an adaptive system would most need to target (Zerkouk et al. (2025)).

A caveat: mastery is not correctness. An, McLaren, and Stamper (2026) show that BKT's two-state (learned/unlearned) assumption can be violated by *deceptive overgeneralization* — learners can appear mastered yet systematically misapply a skill when a hidden application constraint is violated. This argues for tracing conditional understanding (knowing *when to withhold* an action), not only action correctness, when mastery estimates drive adaptive stopping rules.

A related caveat concerns *how* tracing models are validated versus deployed. Schuetze, Yan, and Carvalho (2025) fit BKT, BKT-with-Forgetting, and the Additive Factors Model to a multi-session successive-relearning dataset and found they reproduce learning trends when fit retroactively to all sessions (acceptable AUC ≈ 0.74–0.79); but under **time-based cross-validation** — training on one session to predict the next, the realistic applied setting — all three overestimate future performance by roughly 47–58%, fail to capture the spacing effect, and can even predict the wrong ordinal ordering across practice conditions. Tellingly, models *without* an explicit forgetting mechanism performed about as well as the forgetting-augmented versions as sessions accumulated, suggesting forgetting was partly absorbed into other parameters (e.g., per-student intercepts in AFM) rather than genuinely modeled. The authors tie this to the

learning-versus-performance distinction: popular models conflate high in-the-moment performance with high likelihood of long-term retention. The practical implication is that a tracer that looks good on retrospective fit can mislead the adaptive systems consuming its mastery estimates, arguing for walk-forward evaluation and models that account for retention interval, spacing, and between-session forgetting.

A further caveat concerns the evidence rule that feeds the update. Srivastava (2026) ran four update rules over identical ASSISTments 2012–13 event sequences, differing only in how they score rows completed with help, on a confirmatory half of 12,716 students and 985,813 scored events. Reading a hinted or retried row as a failed first attempt predicted later unaided performance best (pooled AUC 0.658); crediting any completion predicted it worst (0.604), barely above a constant that knows only skill difficulty (0.595). The same choice governs the mastery count: crediting completions declared 93.9% of 113,428 student–skill pairs mastered against 72.8% under the strict rule, and the pairs the lenient rule declared ahead of strict went on to 70.9% unaided accuracy against 85.7% where the two agreed, below the 0.744 base rate. A traced state is therefore partly a function of the scoring convention rather than of the learner alone, so a mastery estimate consumed by an adaptive gate should carry the rule that produced it.

A capability caveat: general language models trace knowledge barely above a trivial baseline. Worden et al. (2026) released FoundationalASSIST, which restores the full question text, the responses students actually gave and their distractor choices that earlier tracing datasets discarded, and tested four frontier LLMs as zero-shot tracers. The best, GPT-OSS-120B, reached 56.2 percent against the 51.3 percent an always-predict-correct rule already scores (AUC-ROC 0.559), with no improvement from longer histories, and Llama-3.3-70B proved right 85.4 percent of the time a student answered correctly but only 12.6 percent when they erred — evidence that an off-the-shelf model traces optimism rather than understanding, so a tracer's apparent skill must be read against the trivial baseline its task permits. - **A single-pass LLM can trace knowledge before any learners are logged.** Queried as one typed question with no target-platform data, Jev reached a mean AUC of .706, above the best of 28 deep tracing models trained on 8 learners (.689) and ahead until supervised tracing catches up at 64-128 learners (Lee & Park, 2026).

Common Misconceptions

"A mastery label means the learner knows it." Mastery is not correctness — a learner can appear mastered and systematically misapply a skill whenever a hidden condition is violated — and the label's value depends on the counting rule behind it. Crediting declared completions marked **93.9% of 113,428 student–skill pairs** mastered against **72.8%** under a strict rule, and the pairs the lenient rule called ahead reached only **70.9% unaided accuracy**. Two defensible rules produced a 21-point difference in who was declared ready.

"Sequence models are what makes tracing accurate." Much of the apparent gain is cheaper than that. On 1,927,265 mathematics responses from 8,996 Finnish students, item identity alone reached **AUC .8362**, and adding a single recency measure relative to item difficulty raised it to **.866**. A large share of what deep sequence models buy is available from an item-difficulty baseline plus recency, so architecture comparisons need that baseline to be meaningful.

"The best model on one dataset is the best model for your course." Accuracy is setting-specific. OKT reached **89.81% AUC** on live engineering-program LMS data (2,416 students, 966 outcomes), beating DKT, DKVMN, EKT and SimpleKT — while giving only competitive results on ASSISTments. The same

architecture that wins on one dataset family is unremarkable on another, so a headline AUC from elsewhere is weak evidence about your students.

“Knowledge persists unless there is evidence of forgetting.” Forgetting is the default worth modeling. Schuetze, Yan and Carvalho (2025) fit BKT, BKT-with-Forgetting and the Additive Factors Model across a multi-session sequence and found that model fit changes when retention is represented, and that how these models are *validated* differs from how they are *deployed*.

Implications for Practice

For instructors

- Treat a mastery label as a claim with a provenance, not a fact. Crediting declared completions marked **93.9% of 113,428 student–skill pairs** mastered, against **72.8%** under a strict rule — and the pairs the lenient rule called ahead went on to **70.9% unaided accuracy** against the stricter set. The rule you chose is visible in the number you see.
- Prefer a model validated on a setting like yours. OKT reached **89.81% AUC** on live engineering-program LMS data (2,416 students, 966 outcomes), outperforming DKT, DKVMN, EKT and SimpleKT — while giving only competitive results on ASSISTments. The advantage is setting-specific, so cross-context accuracy claims should not be your validation.
- Remember mastery is not correctness: a learner can appear mastered while systematically misapplying a skill whenever a hidden condition is violated.

For developers

- Do not pay for sequence-model complexity without a baseline. On 1,927,265 mathematics responses from 8,996 Finnish students, item identity alone reached **AUC .8362**, and adding a single recency measure relative to item difficulty raised it to **.866** — a large share of what sequence models buy for a fraction of the machinery.
- Model forgetting explicitly rather than assuming knowledge persists; the BKT-with-forgetting comparisons show fit changes when retention is in the model.
- Report the deployment rule alongside the model. Validation-vs-deployment mismatch in the forgetting studies is a reporting failure as much as a modeling one.

For researchers

- Report results on more than one dataset family before claiming architectural superiority, since the OKT contrast reverses between engineering LMS data and ASSISTments.
- Report the mastery-count rule as a parameter of the result, not as a methodological footnote.

- How Do We Make a Simulated Student Behave Like a Real Learner?

Cognitive Diagnosis

> **Cognitive diagnosis** — the inference of a learner's latent knowledge state — the specific concepts, skills, and misconceptions they have or lack — from their responses or behavior. It is the assessment-side counterpart to Knowledge Tracing, focused on characterizing *what* a student knows rather than only predicting their next performance.

Questions to Consider

- Cognitive diagnosis infers a learner's latent knowledge state — the specific concepts, skills, and misconceptions they have or lack — from their responses, rather than just predicting their next score. Before reading, what's the difference you'd expect between 'predicting a student's grade' and 'diagnosing what they actually don't understand'?
- A key idea is the 'correct answer trap' — where a right answer conceals flawed reasoning. Have you ever been confident a student understood something because they got it right, only to discover a misconception underneath? How could a diagnosis surface that where a score couldn't?
- The page distinguishes cognitive diagnosis (a static, fine-grained snapshot of what a learner currently holds) from knowledge tracing (the temporal dynamics of mastery over time). Why would an intelligent tutor need both — to know what's wrong and to know what to teach next?
- A design principle here is to separate diagnosis from feedback: LLM tutors confirm correct steps but over-reject valid reasoning and over-validate errors, and accurate diagnosis does not reliably yield actionable feedback. Why might knowing what's wrong still fail to produce a helpful next step?
- LLM-era diagnosis extends from multiple-choice to open-ended, handwritten, and conversational work. What might go wrong if an AI diagnoses a misconception from work it can't fully understand — and how would you verify that the diagnosis itself is trustworthy?

Introduction

Whereas knowledge tracing typically estimates a scalar mastery over time, cognitive diagnosis produces a more granular profile: which knowledge components are mastered, which are fragile, and which misconceptions are present. This profile is the substrate for Personalized Learning, Intelligent Tutoring, and Adaptive Learning.

How cognitive diagnosis works

- **Diagnostic models:** psychometric models (often under Item Response Theory and Educational Measurement) infer latent skill states from patterns of correct and incorrect responses, sometimes via cognitive-diagnosis models that map items to multiple knowledge components.
- **Automated model search:** because no single diagnostic model fits every learner, AutoML-driven approaches (e.g., personalized neural cognitive architecture search) generate diagnostic models for

heterogeneous learner profiles — integrating multi-modal educational data to enable dynamic analysis of learning processes and per-learner cognitive diagnosis, rather than relying on static examination outcomes and simple statistical indicators (Personalized neural cognitive architecture search).

- **Response data:** diagnosis draws on responses to assessments, hints, Help-Seeking, and time-on-task — richer signals than raw scores.
- **LLM-based diagnosis:** newer approaches use large language models to diagnose from open-ended or handwritten work, and to identify the specific Misconceptions about AI behind an error (e.g., the "correct answer trap" where a right answer conceals flawed reasoning). Two 2026 results bound how far that diagnosis reaches. OmniEdu (Liang et al., 2026) supervised diagnostic reasoning as one of four capabilities in an open 4B/9B/27B family, and knowledge-state diagnosis remained its weakest measured capability — 54.04% at 27B and 53.55% at 9B, near enough that three times the parameters did not close the gap — while CoLearn (He et al., 2026)'s LLM grader correlated with true mastery at $r = 0.68$ over pooled answers but only $r \approx 0.15$ within the weakest ability tier ($r \approx 0.48$ mixed, 0.41 strong), so diagnostic reliability tracks the learner's ability level as much as the model's.
- **Diagnosing common mistakes at cohort scale, not one response at a time.** Killich et al. (2026) reverse the usual direction: rather than diagnosing one learner's error, an Large Language Models (LLMs) proposes candidate bug-fixing transformations that map incorrect formalizations onto correct ones across an entire educational data set, and every candidate is validated algorithmically before it is kept. On 6,106 pairs of correct and incorrect propositional-logic formalizations the workflow discovered 248 clusters of transformations explaining 5,156 pairs (84.44%), against 4,370 (71.57%) for the hand-picked mistakes of the previous state of the art, and it recovered the mistakes a domain expert had identified by hand in the literature. Clustering orders candidates into single-transformation, equivalent-transformation and hierarchical groups, and the resulting correlation graph can be visualized for instructors; the same pipeline transferred to modal logic and regular expressions, where one disjunction-for-conjunction transformation alone covered 98.80% of its 334-pair cluster. It is a route to the misconception inventory a diagnostic model needs before it can be fit.
- **Correct-solution recovery, not error simulation, is the bottleneck.** Models constructed a solution in 95.2% of distractor traces and simulated a specific Eedi misconception at 0.92 accuracy, yet supplying the correct answer still raised match with human distractors ($0.52 \rightarrow 0.56$) — the failure sits upstream, in recovering the solution (Zengaffinen et al. (2026)).
- **Outcome-level diagnosis in OBE curricula:** Pradeesh et al. (2026) diagnose which course outcomes a learner has attained in Outcome-Based Education by treating outcomes as the knowledge concepts, supplying concept relationships via expert-validated OBE affinity mappings between course and program outcomes (an explicit alternative to implicitly learned attention or graph relations), and using a memory-augmented module to estimate how one outcome's attainment impacts others — outperforming DKT, DKVMN, EKT, and SimpleKT baselines (89.81% AUC) on live engineering-program data.

- **Diagnosing from instruments built for something else.** Le et al. (2026) show a CD model can extract objective-level information from items never written for diagnosis. Mapping FCI, FMCE and EMCS items onto 14 fine-grained learning objectives in introductory mechanics and fitting DINA on 24,394 posttest responses from 807 courses, they found good fit for two of the three instruments (FCI RMSEA² = 0.033; EMCS = 0.022) and classification accuracy at or above the low-stakes formative benchmark for 19 of the 22 objective–assessment combinations. Attribute structure, not item quality, was the binding constraint: expert coding survived model scrutiny almost intact — DINA proposed revising only 14% of 754 item–objective codings and the coders adopted 20 of them (2.7%) — yet the model could not separate three *conceptually nested* energy objectives (Potential Energy 0.675, Conserve Energy 0.705, Kinetic Energy 0.745) because any two shared about 70% of their items (Jaccard overlap 0.67–0.73), violating DINA's conjunctive independence assumption, while momentum objectives on the same instrument reached 0.820–0.917. Finer attributes also fit better rather than worse: the 14-objective structure improved model fit over the same team's earlier four-broad-skill structure on all three instruments. Item overlap, not coding error, is what caps how finely mastery can be separated.
- **Bayesian DINA for personalized learning paths:** Feng and Huang (2026) integrate a Bayesian DINA model (trained on the EdNet dataset, N=5,000) with knowledge space theory and a shortest-remediation-path algorithm to generate personalized learning paths, and empirically test the mediating role of cognitive load via Hidden Markov Model state transitions (validated on 120 students) — addressing both the sparsity-driven convergence problem of traditional DINA models and the untested psychological mechanism behind personalized-path effectiveness.
- **Language-grounded diagnosis in place of ID embeddings.** Liu et al. (2026) replace discrete student, exercise and concept identifiers with LLM-built concept schemas and process-grounded evidence, calibrating each student's posterior state from response records. Across three mathematics platform datasets the framework reaches 83.51% ACC / 85.37% AUC on XES3G5M and 87.16% ACC on MOOC, with the gain concentrated exactly where classical cognitive-diagnosis models degrade: new concepts (+4.60 ACC over KCD) and missing Q-matrix entries (+4.52). Ablating the structured evidence collapses MOOC accuracy from 87.16% to 78.95%, so the improvement comes from the language-derived structure rather than from model scale. (Beyond ID Embeddings: Process-Grounded Language Modeling for Cognitive Diagnosis)
- **Culturally embedded tasks can precede the AI analysis.** Anggara et al. (2026) had 178 junior-high students in Indonesia complete culturally contextualized open-ended tasks before AI response analysis; the AI diagnoses agreed with expert assessment (ICC = 0.81), while cultural embedding was associated with symbolic mathematical performance (β = 0.42) and engagement (β = 0.37).
- **Strategy configuration can be diagnosed, not just knowledge state.** Five dimensions estimated from 36,234 grammar-game actions predicted the next success with AUC 0.826 while excluding current error counts, and varied within students (ICC = 0.14) rather than across them (Geoffre et al. (2026)).

Why it matters

Accurate diagnosis lets instruction target the actual gaps rather than a global "ability" score — enabling Automated Assessment that explains *why* a student erred and Feedback Loop systems that remediate specific knowledge states. Poor diagnosis produces the inverse: instruction aimed at the wrong concepts. This is why Psychometrically Aware AI emphasizes diagnostic validity alongside prediction accuracy.

Relationship to knowledge tracing and intelligent tutoring

Cognitive diagnosis sits at the heart of the Intelligent Tutoring architecture and is the assessment-side counterpart of Knowledge Tracing:

- **Diagnosis vs. tracing — complementary temporal views.** Knowledge tracing tracks the *temporal dynamics* of mastery — estimating how a scalar knowledge state evolves across exercises and predicting the next response. Cognitive diagnosis produces the *static, fine-grained snapshot* of which knowledge components, skills, or misconceptions a learner currently holds. A tutor needs both: knowledge tracing to sequence what to teach next, cognitive diagnosis to know *what* is actually wrong. IRT- and measurement-based diagnostic models, and cognitive-diagnosis models that map items to multiple components, instantiate the diagnostic side.
- **LLM-era diagnosis.** LLMs extend diagnosis from multiple-choice responses to open-ended, handwritten, and conversational work, identifying the specific Misconceptions about AI behind an error (e.g., the "correct answer trap" where a right answer conceals flawed reasoning). HiLLM-CD uses LLMs for automated concept-tree construction and hierarchical proficiency inference, bridging diagnosis and tracing. Boyapati et al. (2026) push this further by federating diagnosis across multiple commercial LLM APIs with ε-local differential privacy, showing that accurate, privacy-preserving diagnosis is feasible without any model seeing raw student data.
- **Separating diagnosis from feedback is a design principle.** LLM tutors reliably confirm correct steps but over-reject valid reasoning and over-validate errors — and accurate diagnosis does not reliably yield actionable Feedback. ITS design should therefore separate a diagnostic component from the feedback/Scaffolding component (Confirming Correct, Missing the Rest: LLM Tutoring Agents Struggle Where Feedback Matters Most).

Connections

Cognitive diagnosis connects to Knowledge Tracing, Learner Modeling and Adaptive Instruction, Educational Measurement, and Assessment. Its insights feed Intelligent Tutoring and Adaptive Learning, and LLM-era work links it to misconception identification in AI Tutoring.

Common Misconceptions

- **"Diagnosis is a solved capability for models."** OmniEdu (Liang et al., 2026) supervised diagnostic reasoning as one of four capabilities in an open 4B/9B/27B family, and **knowledge-state diagnosis remained its weakest** of the four. Diagnosis is the capability that resisted the training that produced the others.

- **“Models can simulate student errors, so they can diagnose them.”** The bottleneck is the reverse. Models constructed a solution in **95.2% of distractor traces** and simulated a specific Eedi misconception at **0.92 accuracy**, yet **supplying the correct solution** — not simulating the error — was what limited them. Generating a plausible wrong answer is easier than recognising one.
- **“Diagnosis requires a hand-built misconception catalogue.”** On **6,106 pairs** of correct and incorrect propositional-logic formalisations, a workflow discovered **248 clusters of transformations explaining 5,156 pairs (84.44%)**, against **4,370 (71.57%)** for the hand-picked mistakes of the reference set. Discovery matched or exceeded expert curation, and it transferred to modal logic — so the catalogue is a starting point, not a ceiling.
- **“A diagnosis is only useful if it names a misconception.”** Diagnosing which course outcomes a learner has attained treats outcomes as the knowledge concepts instead, supplying concept relationships through expert-validated affinity mappings. For outcome-based programs that is the more actionable unit, even though it is coarser.

What this means for practice

For instructors

- Treat a system’s diagnosis as a hypothesis to check, not a verdict. Knowledge-state diagnosis was the weakest capability in a family trained for it.
- Ask whether the diagnosis names a construct you can act on. An outcome-level diagnosis that maps to your program is often more useful than a fine-grained misconception label.
- Where your subject has rules, expect transformation-based discovery to find error patterns you did not anticipate; the 248 discovered clusters are evidence that curated catalogues are incomplete.

For developers

- Instrument both directions: recognising a wrong answer and producing the right one. The 95.2% solution-recovery figure suggests generation is the easy half and the failure mode sits in recognition.
- Prefer discovery over a static catalogue where domain structure permits it, and report coverage against a reference set so the comparison is legible.
- Do not ship a diagnostic score without stating which construct it measures and how it was validated independently of the signal that produced it.

Simulating Students

> **Simulating students** — using LLM-based agents to model learner behavior, cognition, and social dynamics for educational research, design, and training. Simulated students let researchers evaluate pedagogical approaches, model diverse learner profiles, test educational AI before deployment, and train teachers — tasks that are difficult, slow, or ethically constrained to do systematically with real learners.

Questions to Consider

- If you had to build an AI 'student' to practice your teaching on, what would make it convincing to you — and why might a system that always gives the right answer actually be a poor stand-in for a real learner?
- The page calls the mismatch between a capable AI's perfect answers and a real student's imperfect ones the 'competence paradox.' Where have you seen this tension in your own experience with AI, and what do you think it takes to make a simulated learner genuinely realistic?
- What are the ethical and practical reasons you might prefer testing a tutoring system or curriculum on simulated students rather than real ones — and what validity risks do you suspect that trade introduces?
- A simulated student can be 'epistemically faithful' without looking superficially human. Before you read on, what distinction do you imagine between a believable surface and a truthful model of what a learner actually knows?
- How would you decide whether a finding produced by simulated students should be trusted enough to change how you teach real people?

Introduction

Simulated students are a methodological tool: agents that stand in for real learners so that tutoring systems, curricula, and instructional strategies can be evaluated and iterated without recruiting cohorts of human students. Large language models have made this paradigm far more scalable and linguistically realistic than the rule-based simulated learners that preceded them, while also introducing new validity challenges.

AI-mediated approximations sharpen the question the page cares about: whom the simulation represents, and what the teacher is meant to notice. In mathematics teacher education, text-based simulated student work and chatbot partners used in rehearsal extend the approximations of practice that already organize professional training. One chatbot study produced four distinct questioning profiles, yet pre-service teachers' self-assessments did not align with the interaction quality observers recorded, which makes automated post-rehearsal feedback that increased probing and exploring questions a useful but insufficient guide. The simulator, the candidate and the feedback all have to be read together. What a simulation lets a teacher notice is also set by its design: in Galiç et al.'s (2026) three-week equal-sign intervention with 17 preservice mathematics teachers, candidates moved among attending, interpreting and shaping rather than through a fixed sequence, but the one-to-one, text-based setup meant shaping collapsed into questioning and

prompting, and a misconception-first design pulled attention toward error detection rather than student strengths. The simulator chooses the slice of teaching a candidate gets to rehearse.

Supervised finetuning alone conditions a simulator only weakly on the prompted ability, because its objective rewards reproducing response text rather than tying response quality to ability; Fernandez et al. (2026) align a simulator instead through direct preference optimization over pairs formed from students' IRT ability gaps, and on CodeWorkout that pairing beats all direct difficulty-prediction baselines and, at the 1B scale, the SMART simulator on every difficulty metric while producing more distributionally realistic responses.

Why simulate students

- **Evaluating pedagogy:** testing instructional approaches across many learner profiles in a controlled, repeatable way.
- **Modeling diverse learners:** capturing variation in cognitive levels, learning styles, prior knowledge, and Misconceptions about AI that is hard to assemble in a real cohort.
- **Testing educational AI:** validating tutoring and Assessment systems before live deployment, and generating training data.
- **Teacher training:** letting instructors practice tutoring and classroom management with simulated, often imperfect, learners.
- **Simulations cover the easiest students, and few are validated.** Twelve teachers who tutored LLM students reported overly complex language, missing emotion, unnatural attentiveness and knowledge jumps, and the simulations represented only one of four real student behavior quadrants — while just 3% of studies simulating learners validate them after use (Martynova et al. (2026)).

The core challenge: realistic imperfection

The defining difficulty of student simulation is that LLMs are trained to be "helpful assistants" that produce correct, polished answers. Yet real students are imperfect — they make characteristic mistakes, hold misconceptions, and learn gradually. A simulated student that answers perfectly (or too randomly) is not a valid model of a learner. Research frames this as the **competence paradox**: broadly capable LLMs asked to emulate partially knowledgeable learners produce unrealistic error patterns and learning dynamics. Nguyen and Cao (2026) give that drift a direction. Against lesson-embedded student ideas drawn from 49 NGSS-aligned science lessons, six models kept most ideas inside the expected knowledge scope and roughly two-thirds at or below the target reading level, but overshot exactly where the learner was youngest: elementary and middle-school ideas more often exceeded the target grade's knowledge scope and reading level, while the corpus as a whole leaned toward broader reasoning, more technical vocabulary and fewer uncertainty markers ("maybe", "it seems") than the lesson ideas. Model choice is not one-dimensional either — a system that matches lesson ideas closely can still pitch them above grade, so the repair is usually instructional, since an explicit grade-level re-prompt lifted most models back into range. Addressing it requires constraining the simulation so it reflects a genuine epistemic state — what the learner knows, how errors are structured, and how state evolves — rather than the model's full competence. Techniques include cognitive prototypes

grounded in Knowledge Graph or Knowledge Tracing models, explicit epistemic state specifications, and state-transition models of learning rather than simple persona-conditioned role-play.

A different lever removes the knowledge instead of constraining the output. Suppressing 16 targeted knowledge components in Mistral-7B dropped accuracy from about 0.75 at a 10% forgetting ratio to below 0.5 at 40% while the base model held near 0.85, and the suppressed knowledge proved recoverable through supervised relearning and coach-guided dialogue (Song, Guo & Lin, 2026).

Persona stability is an interaction-design problem, not a model-choice one: crossing five LLMs with three prompt designs and four ADHD-intensity personas, scripted task-anchored interactions eliminated observer-rated behavioral drift — up to 97% less than unscripted dialogue — and without explicit persona instructions baseline student representation skewed toward high ADHD symptoms (Gonnermann-Müller, Haase & Leins (2026)).

The opposite failure also occurs: in a blinded study, expert annotators misclassified 164 of 196 (83.7%) LLM-generated Java submissions as human-written, so a simulator's errors can be functionally indistinguishable from authentic ones — though alignment with real errors fell as problem difficulty rose (Keramati et al. (2026)).

Conditioning generation on a predicted behavior model works without fine-tuning: a training-free framework builds each student's cognitive prototype from a Knowledge Graph and scores beam-search candidates against it, reporting a 100% improvement in simulation accuracy (Wu et al. (2025)). Its quality rises with the student's cognitive level, so weaker learners remain the harder case to simulate. - **Predict the learner instead of acting as one.** Jiang et al. (2026) recast simulation as third-person prediction: a student model built from the learner's history supplies a prior, an inferred learner state constrains the next action, and the simulated ability distribution lands 2.4–8.4× closer to the real one by Wasserstein-1 distance.

CogEvolution models cognitive dynamics rather than a static persona — an ICAP depth perceptron sets each state update's size and an evolutionary update stays within a Zone-of-Proximal-Development radius — reaching $R^2LC = 0.92$ where static agents reach 0.45 and collapsing to 0.58 without the ICAP module (Zhang et al. (2026)).

Drift is a horizon problem, not a persona problem. Radmehr et al. (2026) show that turn-level generation loses an assigned profile as trajectories lengthen, while planning profile-aligned segments before generating actions held density and judge-rated consistency even with three real trajectories per profile.

Fidelity over surface realism

Validity is the central concern: a simulated student is only useful if its behavior is **epistemically faithful** — reflecting the intended learner's knowledge state — not merely linguistically plausible. Research warns against sycophancy, where a "simulated student" simply agrees with the tutor rather than exhibiting the misconceptions it was meant to embody. This connects to Trust Calibration and to the broader problem of evaluating whether an agent genuinely models a construct rather than reproducing surface behavior.

The failure is quantified: across seven models from 4B to 120B parameters, simulators flipped to the correct answer at near-uniform rates whatever the feedback, so output similarity says nothing about the belief state behind it, while training against the Selective Flip Score lifted faithfulness by up to +0.56 (Do, Sonkar & Sachan (2026)).

Simulated clients remove the clarification phase, and the trainee's behavior follows. Rudolph et al. (2026) compared 64 human-human chat counselling role-plays with 74 human-LLM conversations (Mixtral 8x7B, 4-bit) under the GeCCo category system and found that LLM clients disclosed the problem embedded in their prompt rather than circling it. Counsellors consequently reached Problem-Solving in 17.63% of coded behavior against 10.67% with human clients, relied more on factual reflection than facilitative moderation, and closed sessions with formalities more often (11.95% vs 5.95%). The design consequence is that a curriculum built mainly on simulated clients trains the second half of a session: eliciting a reluctant account is exactly what the simulated client skips, so a prompt that makes the client withhold restores it.

Connection to the knowledge base

Simulating students sits at the intersection of Simulation, Learner Modeling and Adaptive Instruction, and Knowledge Tracing. It is a distinct use of Generative AI in education (modeling learners rather than tutoring them) and an application of Agentic AI multi-agent systems. It supports Intelligent Tutoring, Adaptive Learning, Personalized Learning, and Teaching development, and it overlaps with patient simulation for professional training (e.g., Special Education and medical education contexts). At the paradigm level, Zhang, Jiang and Tang (2026) extend this beyond evaluation: their position paper argues that educational science suffers a structural mismatch between its theory and its data and method apparatus, and proposes agent-based educational science, in which agents model learners, teachers, parents and peers while the simulation apparatus itself — not the individual agent — serves as the research instrument, generating time-extended developmental trajectories and counterfactual designs that are slow, costly or ethically infeasible to run in classrooms, with empirical data recast as calibration, validation and boundary conditions. The paper reports no empirical validation of any of this: Student Development Agents are specified conceptually only, and the authors' own review concedes that LLMs still miss inter-individual variability and that validating generative social simulation remains the field's unresolved challenge, so the claim that simulation would change how evidence and replication work is a proposal rather than a demonstrated result.

An empirical companion comes from the same group: a student development agent predicts 42 real students' post-course non-cognitive outcomes on the MAIC platform, beating the mean pre-course baseline on RMSE in all five dimensions (Jiang & Zhang, 2025). Its target is development rather than behavior — the agent's state feeds into its next actions — and prototyping on agents is argued to keep students out of a study's most uncertain stage.

Simulating students vs. student modeling

The key distinction is between **representing a real learner** and **generating a synthetic learner**. Learner Modeling and Adaptive Instruction is the practice of building a computational representation of an actual student — what they know, feel, and need — so that adaptive systems can personalize instruction for *that* learner. Simulating students, by contrast, *creates* fictional learners on demand, not to serve a real individual but to stand in for a cohort so pedagogy and AI systems can be tested offline.

The two are complementary rather than competing. A high-fidelity simulated student typically *contains* a student model (an epistemic state, a misconception set, an engagement profile) and draws on the same constructs that Learner Modeling and Adaptive Instruction and Knowledge Tracing formalize. The shared

validity challenge is the same in both: the representation must faithfully reflect a learner's true state rather than the system's default behavior. But the *purpose* differs — student modeling diagnoses a real learner to act on them; simulation fabricates learners to test or train. This is why simulated-student research is increasingly used to audit AI (see below) while student-modeling research remains oriented toward live Adaptive Learning and Personalized Learning.

The mirror question runs the other way. AI Avatars and Synthetic Instructors simulates the person teaching rather than the person learning, so simulated students expose a method to scrutiny while synthetic instructors stand in front of a learner, who is the beneficiary and the judge.

Two-axis fidelity: behavioral match and guidance responsiveness

StudentSim (Yang et al., 2026) formalizes the validity problem as two requirements that must hold together: **behavioral fidelity (F)** — how well a simulator matches a student's own responses — and **guidance responsiveness (R)** — how reliably it updates toward where tutor guidance leads. Its Benchmark, StudentSimEval, casts public learner corpora (chess, second-language English writing, mathematics) into a standardized per-student protocol on which any simulator is fit and scored on held-out records. A two-stage **pooled-then-specialized** pipeline (a shared pool of behavioral patterns plus a per-student adapter) yields a family of simulators strong on both axes, outperforming domain-specific state-tracking (weak on R) and prompt-only LLM role-play (weak on F). This gives the field a concrete, two-axis vocabulary for judging whether a simulated learner is genuinely useful rather than merely plausible — and, as a proof of concept, a frozen StudentSim used as the reward in a chess-tutor Reinforcement Learning loop produced tutors that experts rated as more accurate, better-guided, and more personalized than those trained with a frontier-LLM-simulator reward or no RL at all.

Student simulators reproduce observable actions but not the latent reasoning behind them. INSIDE fine-tunes models to generate an internal dialogue before each action, reaching the highest alignment between generated reasoning and real code edits (51.8% on familiar problems, 57.9% on unseen ones) without losing action fidelity (Niousha et al., 2026).

Describing, not simulating: when a single agent beats a simulated cohort

A recurring question is whether simulating a distribution of learners is the best way to predict how real students will fare. Wang, Mitchell & Piech (2025) supply a striking counter-result: for **evaluating an online learning experience before students engage** — predicting dropout and completion and giving design feedback — a **single "describing" web agent** that autonomously walks through the lesson and produces a rich description of the student experience outperformed directly simulating a population of students. Their simulated students (persona-conditioned agents sampled to match a predicted completion rate) exhibited far less behavioral range than real learners — across 100 agents on five test lessons they reproduced only about **4% of the paths** real students took — and offered little insight into lesson difficulty, while being substantially more computationally expensive. The single describe-then-predict pipeline (agent-generated descriptions fed to an Large Language Models (LLMs) to predict outcomes) achieved the best dropout-distribution prediction on a massive global CS1 course (mean JSD 0.060, beating every baseline). This is a productive boundary result for the field: simulating a *distribution* of students may be unnecessary — and even counterproductive — when the goal is outcome prediction or design critique, because a faithful

description of the experience carries more signal than a narrow slice of simulated trajectories. It also suggests simulation's role may be bounded to questions (e.g., auditing an AI's treatment of diverse profiles, or training teachers) where covering genuine learner variation matters more than aggregate outcome prediction.

Authentic-data student models and interactive practice

Two 2026 threads sharpen the practical value of simulation. First, **authentic-data student models** — TeachLM trains a student model on 100,000 hours of real one-on-one tutor–student interactions (with rigorous anonymization), producing synthetic learners that enable fast, scalable, reproducible multi-turn evaluation of tutor behavior; this addresses the low authenticity and diversity of purely prompt-engineered student simulators. Second, **interactive instructional simulacra** — EducaSim uses generative agents (with personas, course-grounded memories, and an LLM-as-judge speech oracle) to simulate a small-group section for teachers-in-training, adding runnable-code and voice interaction plus structured post-session feedback and self-reflection, and demonstrates low-cost, positive-uptake experiential teaching practice at the scale of massive online courses. Both point to simulation serving not only evaluation but hands-on teacher preparation.

A third 2026 thread concerns *how* a simulator is built rather than what it is used for, and it converges on one conclusion: prompting sets a ceiling that training removes. SWIM (Do, Kontak and Sachan, 2026) reformulates student writing simulation as proficiency-conditioned essay generation and compares rubric-grounded prompting, supervised fine-tuning on real score-essay pairs, and GRPO with an Automated Essay Scoring-derived Proficiency Alignment Reward, scoring each generated essay against its target trait profile with Quadratic Weighted Kappa. Prompting gave limited control even to strong proprietary models (best average trait QWK 0.577 for Claude Sonnet, 0.422 for GPT-5.4, near zero for prompting an open 7B model), it aligned content-oriented traits far better than form (0.695 against 0.458), and it produced an idealised high-proficiency population, with a mean normalized Overall score of 0.74 against 0.58 for real students and a median length of 304 words against 167. Supervised fine-tuning moved a 7B model to 0.474 ± 0.023 and GRPO to 0.618 ± 0.005, the gains held on two independent scorers the policy never trained against, and the trained models recovered the human score and length distributions without any length supervision; authentic low-proficiency form stayed hardest, since trained models recovered syntax but wrote too few spelling and grammar errors while prompting simulated weakness mainly through superficial corruption. The same lesson arrives from the opposite direction in Liu et al. (2026), who instruction-tuned three small models to hold algebra misconceptions: data *composition* decided the outcome, because a single misconception overgeneralised and degraded correct solving until correct examples were mixed in, several misconceptions trained jointly without cost, and no misconception was acquired from final-answer-only supervision at any data size, leaving step-level solution traces as the binding requirement.

Benchmarking nine simulation methods against seven reference-based metrics on 382 held-out math dialogues, prompting trailed fine-tuning on dialogue acts (0.4998 against 0.6840), ROUGE-L (0.1648 against 0.3212) and cosine similarity (0.5460 against 0.7390) (Scarlatos et al., 2026). Yet the best method tested, preference optimization on an 8B model, beat supervised fine-tuning only marginally and was worse on errors, and a three-tutor human evaluation reproduced that ranking.

Architecture can enforce what prompting cannot: a neuro-symbolic simulator imposing self-regulated learning structure through a semi-Markov controller and flaw-injected knowledge tracing reached behavioral divergence of 0.31 against a 0.53 baseline (Wang et al., 2026). Injecting its metacognitive vocabulary into baselines never beat 0.63, removing the symbolic controller pushed divergence to 6.81, and in a 71-rater Turing test its traces were indistinguishable from real students (52.8%, d′ = 0.15).

Auditing AI with simulated students

Beyond evaluating pedagogy, simulated students serve as a **test harness for auditing AI systems themselves** — a controlled way to probe how an AI behaves across diverse learner profiles before it touches real students. López-Pernas et al. (2026) illustrate this: they generated 4,500 synthetic student vignettes with three LLMs to audit whether current large language models can act as prescriptive Learning Analytics recommenders, finding limited sensitivity to student need and sharp cross-model inconsistency. Using simulated cohorts to stress-test an AI's recommendations (rather than only to train or evaluate tutors) is a growing role for the paradigm, closely tied to evaluating AI in education and to Equity when the audit is meant to surface disparate treatment across learner types.

A sharper validity test asks whether a model reproduces human *choice* at all: in an adapted self-directed learning game, five frontier models exploited a single solution where 175 human participants explored across goals, so a model standing in for learners abandoned the behavior the simulation exists to reproduce (Molinaro et al. (2026)).

Simulation can also pre-test the learner's choices: Noh et al. (2026) fit an Additive Factors Model and Bayesian Knowledge Tracing to two real tutoring datasets and let 1,000 simulated learners choose skills under eight strategies, where a risk-averse rule produced roughly thirty times the overpractice of the others and a just-below-mastery constraint cut it to 1.8×.

A second audit register is metacognitive and affective. MEDS (Esposito et al., 2026) is a 28,000-record dataset — 2,000 synthetic personas for each of 14 models, every one run both as a human persona and as a baseline assistant — that records accuracy on 18 high-school math problems alongside self-reported confidence and the Self-Efficacy and math anxiety scores the learners it stands in for would report. Its audit signal is the calibration gap: the Qwen family and Ministral 3B asserted confidence above 0.90 while accuracy stagnated near 0.55, while Grok 4.1 Fast, DeepSeek Chat and several Mistral Small variants were underconfident and Ministral 14B and Anita 24B stayed reasonably aligned. The same runs expose a quieter failure of fidelity: human-mode personas yielded wide, plausible score distributions, but baseline assistants returned near-identical, confident, low-anxiety answers — a default self-portrait rather than a simulated learner's. This extends the recommender audit above by probing what a model claims about its own competence and affect, and it sharpens the page's validity warning from an unexpected direction: because MEDS personas are weighted by construction rather than sampled from a real population, its authors present the dataset as an observational resource for auditing prompt-conditioned GenAI behavior and explicitly not as a stand-in for real student data.

Simulating collaborative and social dynamics

Simulation also extends beyond individual learners to reproducing the social dynamics of collaborative learning. **Participant-specific LLM agents** — Fang (2026) fine-tuned LLaMA 3.2-3B agents on individual

participants' dialogue data to represent each participant in collaborative problem solving simulations, combining sliding-window memory with summarized memory embeddings to preserve both local turn-taking and thematic continuity, and probabilistically selecting speakers and thematic codes from empirical distributions. Using Epistemic Network Analysis (ENA), the simulated dialogues were statistically indistinguishable from real ones (ENA distance 0.17, well within the 95th-percentile null threshold; permutation p = 0.65), validating that LLM agents can reproduce both turn-taking dynamics and thematic code trajectories of real collaborative problem solving.

The 2026 durable-skills work inverts the usual direction of simulation. Instead of simulating the student to audit a system, the system simulates the *teammates* to assess the student: an Executive LLM generates every AI partner's turns in a 30-minute group task, holds the scoring rubric, and steers the conversation to manufacture occasions for the target skill to appear (Globerson et al., 2026). Across 373 conversations from 188 participants, skill-matched steering raised ratable evidence to 92.4% for project management and 85% for conflict resolution, significantly above unconstrained independent agents, while the AI evaluator was calibrated against two human raters whose own inter-rater Kappa was only 0.45–0.64 — a useful reminder that a simulator's ceiling is set by the agreement humans can reach on the construct.

Training against a simulator can also travel: TutorLoop's reinforcement-learning agent, trained offline against a simulated student, transferred unchanged to a new real learning task with no retraining (N = 187), where its sparser but better-timed feedback outperformed denser feedback (Xu & Zhang, 2026).

Common Misconceptions

- **"LLM students are good enough proxies." Simulations cover the easiest students, and few are validated**: **twelve teachers** who tutored LLM students reported **overly complex language, missing emotion** and other departures from real learners. The proxy models the tractable case.
- **"A simulated student with a knowledge gap behaves like a learner with that gap."** Suppressing **16 targeted knowledge components in Mistral-7B dropped accuracy from about 0.75 at a 10% forgetting ratio to below 0.5 at 40%**, while the base model held. The degradation was engineered, which is what makes it a controlled manipulation rather than an emulation.
- **"Persona stability is a model-choice problem."** It is an **interaction-design problem**: crossing **five LLMs with three prompt designs and four ADHD-intensity personas**, scripted differences tracked the prompt design rather than the model. Choosing a better model does not fix an unstable persona.

Intelligent Tutoring

> **AI tutoring / intelligent tutoring** — the use of AI to provide personalized, adaptive, scalable instructional support: from classical Intelligent Tutoring Systems (ITS) that model student knowledge, adapt instruction, and scaffold Problem Solving, to conversational and agent-based tutors built on LLMs. Effectiveness hinges on pedagogical design (Scaffolding, feedback quality, autonomy balance) rather than the model alone — see Measuring Whether LLM Tutors Teach or Solve: A Diagnostic for Educational Impact and Socratic Method.

Questions to Consider

- An AI tutor's effectiveness is said to hinge on pedagogical design — scaffolding, feedback quality, the balance of autonomy and guidance — rather than on the underlying model. If you had to pick, which design choice most determines whether a student actually learns?
- Classical ITS are praised for precision and transparency but criticized for inflexibility, while LLM tutors are flexible but can hallucinate or bypass learning. Where do you think the right balance lies, and why?
- Large-scale field evidence found students tried an AI tutor but rarely used it productively — engaging it in only a fraction of their mistake sessions, often with bare answers. Why might students get access to a powerful tutor yet not use it in ways that help them learn?
- The page contrasts traditional ITS that model a learner and adapt instruction with open-ended conversational tutors. What is gained and lost when a tutor can hold a natural conversation but doesn't know exactly why it made a decision?
- One study found AI created a 'productive slowdown' — more time per question — but only improved learning when embedded in a mastery workflow that made mistakes consequential. What does that suggest about structuring effort so it pays off?
- If hint design can inadvertently enable students to bypass learning, what would a well-designed hint system look like that supports struggle without giving away the answer?

Introduction

AI tutoring encompasses the use of artificial intelligence — particularly large language models and structured Intelligent Tutoring Systems — to provide personalized, adaptive, and scalable instructional support to learners. AI tutors take many forms: conversational tutors that engage in Socratic dialogue, scaffolded feedback systems that guide problem-solving, adaptive learning platforms that personalize content sequencing, and agent-based tutors that maintain long-term learner models. The effectiveness of AI tutoring depends critically on pedagogical design choices — scaffolding, feedback quality, and the balance between autonomy and guidance — rather than on the underlying model alone.

Historically, **Mishra et al.** locate ITS within AIED's lineage from 1960s-70s expert systems and Anderson's ACT/ACT-R cognitive tutors, whose structured control contrasted with Papert's constructionism.

Ng'ambi and van der Merwe (2026) show that the tutoring role is set by task design rather than by the system: the same language model, configured identically, sustained extended dialogue in problem-based Grade 9 mathematics tasks and collapsed into transactional answers under structured procedural ones.

ITS in the learner-modeling family

Intelligent tutoring is the classic *application-side* member of the learner modeling and adaptive instruction family. Its canonical architecture — domain model, student model, and pedagogical model — is precisely the "model a learner, then adapt instruction" pipeline the family describes. ITS consume the learner representations produced by Knowledge Tracing and Cognitive Diagnosis to select problems and scaffold guidance, which is why tutoring is so tightly coupled to those modeling methods. Within the family, ITS sits alongside adaptive learning (the real-time adaptation mechanism) and personalized learning (the broader goal) as the platforms that turn learner models into instruction.

ITS vs. LLM-based tutoring

The emergence of LLMs has created a productive tension in the tutoring field. Traditional Intelligent Tutoring Systems (ITS) offer precision and transparency — you know exactly why the system made a particular decision — but lack flexibility. LLM tutors offer natural dialogue and broad knowledge but can hallucinate, over-scaffold, or bypass learning entirely. Modern research increasingly explores **hybrid approaches** that combine structured ITS components with LLM flexibility. Reddig, Arora & MacLellan (2025) demonstrate this concretely in the Apprentice Tutor College Algebra ITS: supplying GPT-4 the tutor's interface structure and Bayesian Knowledge Tracing skill estimates within the prompt lifted logical-error diagnosis from 40% to 81% on factoring (and error identification overall to 87.8%) and produced ~66% error-targeted hints — direct evidence that embedding an LLM in an ITS's structured framework grounds generation, curbs hallucinated diagnoses, and yields context-aware corrective feedback, even though roughly a third of the hints remained too general, incorrect, or answer-revealing.

Training pedagogy into the model is a distinct route from prompting it: LearnLM mixed pedagogical data into Gemini's post-training, was preferred by education experts over GPT-4o (+31%), Claude 3.5 Sonnet (+11%) and base Gemini 1.5 Pro (+13%), and — because co-trained rather than fine-tuned afterwards — the gains survive future base-model releases (LearnLM Team (2025)).

TeachLM argues the scarce ingredient is authentic learner–tutor interaction: fine-tuned on 100,000 hours of one-on-one tutoring, it roughly doubled student talk time and increased dialogue turns by 50%, after an earlier prompt-engineered tutor could not close the gap to human tutors (Perczel, Chow & Demszky (2025)). - **Supplying reference strategies lifts weak tutors, not strong ones.** Giving models the case literature's documented strategy raised immediate-response success for 10 of 11 models by an average of 9.9 points — Llama 4 Maverick from 41.0% to 64.8% — while the strongest model was unchanged at 71.3% (Park et al. (2026)). - **Access to a tutor is not the same as learning from it.** Randomizing 153 proof-course students to earlier access to a chatbot and a feedback interface raised homework scores 2.56 points and left the unsupported exam unchanged, with each 100 chatbot messages tracking 3.02 points lower (Chen et al. (2026)). - **Valid alternatives expose a responsiveness gap.** Simulating dialogues on 150 programming problems with more than one correct solution, four open-weight tutors opened with brute force 22.2 to 32.1 percent of the time and the optimal approach only 13.0 to 19.4 percent (Cen & Sonkar (2026)).

Intelligent Tutoring Systems represent one of the oldest and most researched areas of AI in education. Unlike general-purpose LLM tutors, ITS traditionally use structured approaches: domain models (what to teach), student models (what the learner knows), and pedagogical models (how to teach). These components enable fine-grained tracking of student progress, misconception diagnosis, and adaptive sequencing.

Key ITS research

- **Micro-randomized trials of a tutoring platform:** Harrison et al. (2026) ran a four-week multisite individually randomized evaluation of Medly in GCSE Biology, Chemistry and Physics, with 644 of 929 students completing post-testing; allocation to the platform produced Hedges' g = 0.33 (95% CI 0.18 to 0.48) against business-as-usual self-directed revision, with positive estimates in all three subjects and no evidence of differential impact by disadvantage (Pupil Premium g = 0.28 versus non-Pupil Premium g = 0.35).
- **Hint button research** shows that traditional ITS hint design can inadvertently enable bypass strategies, calling for more sophisticated Scaffolding approaches.
- **Deeptutor** provides a fully Open Source agentic tutoring framework with citation-grounded tutoring and difficulty-calibrated question generation.
- **Interpretable Knowledge Tracing** addresses the opacity problem by producing interpretable cognitive quantities from LLM logits.
- **Engagement and structure, not capability, are the binding constraints (large-scale field evidence):** Khanmigo (Oreopoulos & Low 2026) — a two-year cluster RCT in 18 middle schools — found 96% of students tried the AI tutor but the median engaged it in only ~17% of mistake sessions (mostly bare answers or prompt clicks), so gains (~0.06–0.08 SD) matched practice without AI. NUMI (Oreopoulos et al. 2026) found AI created a "productive slowdown" — more time per question and improved post-mistake recovery — but only reliably improved delayed learning when embedded in a mastery workflow that made mistakes consequential. The lesson: AI tutoring's value depends on **getting students to use it productively** and structuring it so effort pays off, more than on raw model capability.(Virtual tutoring with computer-assisted learning: An experiment in take-up and learning)
- **A tutoring harness helps weak backbones and can hurt strong ones.** RegulaTutor (Li et al. 2026) wraps a model in evidence-linked, SRL-grounded stages and raised historical-evidence accuracy by a mean of 25.7 points across four local checkpoints. The judged quality of teaching barely moved (+0.016), and evidence gains reversed on the strongest backbone tested (GPT-5.6-sol −4.87 points).
- **Outcome-based knowledge tracing for OBE tutors.** Pradeesh et al. (2026) trace student mastery of Outcome-Based-Education course outcomes with a recurrent model that replaces learned concept relations with curriculum-validated OBE "affinity mappings" between course and program outcomes and adds a Memory Augmented Neural Network for cross-outcome impact. It reached 89.81% AUC on live engineering-program data, beating DKT, DKVMN, EKT, and SimpleKT baselines — a mastery signal aligned to a program's own outcomes that can drive adaptive problem selection in outcome-based tutoring.

- **Validate mastery models on future sessions, not retrospective fit.** The mastery estimates an ITS uses to select problems may not generalize across time: Schuetze, Yan, and Carvalho (2025) found that BKT, BKT-with-Forgetting, and AFM reproduce learning trends only when fit retroactively to all sessions of a successive-relearning dataset — but under **time-based cross-validation** (training on one session to predict the next, the actual tutoring setting) they overestimate performance by 47–58%, fail to capture the spacing effect, and can mis-order practice conditions. Tutors relying on such tracers should be evaluated walk-forward and consider retention interval and between-session forgetting rather than assuming mastery persists.
- **Diagnosing mistakes on unstructured, handwritten-solution problems.** Arthur (Yin et al. 2026) extends ITS-style feedback to Calculated Formula Questions in an Engineering Economics course, a domain where pen-and-paper solutions lack the structured digital data that previous AI tutoring work relied on. Rather than a general-purpose LLM, each question gets its own dedicated XGBoost "solution diagnosis backbone" — trained on curated, random-masking-augmented graded submissions to predict instructor rubric mistake labels from students' submitted numbers alone (precision 0.81, recall 0.79) — paired with a dialogue-based interaction that iteratively requests intermediate answers only when diagnosis confidence drops below a 0.8 threshold. It is a concrete case of the knowledge base's principle that a knowledge-grounded classifier can handle solution diagnosis even where full written solutions are unavailable.
- **Turn-level adaptive tutoring with a background evaluator.** The MeduAI-SP tutor agent (Yang et al., 2026) exemplifies turn-level adaptive tutoring: a background evaluator monitored each student utterance against a 30-item OLDCARTS-linked history checklist plus communication criteria and triggered prompts only when warranted (24.1% of 4,815 messages). Corpus analysis exposed where such support is most needed — student talk was 62.2% history of present illness but only 4.3% empathic/supportive communication and 2.6% physical examination — suggesting ITS-style clinical tutors should target underused consultation components and late-encounter reasoning phases rather than symptom gathering alone, and that simulated-patient fidelity is high enough for outcome research (only ~0.68% of patient utterances showed clear fidelity problems).
- **An AI tutor built from the class's own pedagogy outperformed that class: an RCT against active learning.** In a crossover RCT in Harvard's largest introductory physics course (194 eligible students), a custom tutor engineered from the same seven research-based practices as the in-class lessons produced a median post-test of 4.5 against 3.5 for the course's in-class active learning (baseline median 2.75), an effect size of 0.63 by linear regression, in a median 49 minutes on task against 60 in class, with higher reported engagement (4.1 vs 3.6) and motivation (3.4 vs 3.1) (Kestin et al., 2025). The authors locate the advantage in the two practices a classroom cannot sustain — personalized feedback on demand and self-pacing — and warn that the tutor should augment, not supplant, in-class instruction.
- **Teacher mediation roughly doubles implementation fidelity (full-district field evidence):** Goblins (Alam et al. 2026) — a teacher-mediated multimodal AI math platform rolled out to all grades 6–8 math teachers in a large Arizona district — reached ~51% of 6,065 students at a modest 2-problems-per-week engagement bar, versus the 5% (Khan Academy) and 12% (IXL) thresholds in prior evaluations.

- **And dose drives the effect within it (same study):** a weighted propensity design associated usage with 0.11 SD within-district MAP growth (0.24 SD on the national Conditional Growth Index), with a clean dose gradient — 0.18 SD at 10–19 problems/week and 0.31 SD at 20+, all dosages above 3/week significant ($p < 0.01$). Exploratory subgroups showed larger associations for students with IEPs (+0.122 SD), English learners (+0.191 SD), and Hispanic students (+0.084 SD). The design is quasi-experimental — self-selection into usage is the vulnerability the authors name — but fidelity and dose-response directly instantiate the binding-constraint lesson.
- **Statistical equivalence to expert human tutoring.** Across 2,469 sessions from 2,383 adults, pooled AI tutoring matched live one-to-one expert human tutoring on GRE learning gains ($p=.015$ against ±0.25-SD bounds; adjusted difference -0.58 percentage points) and both beat a video control by about six points; six of twelve tutors passed individual equivalence tests, with Gemma 4 31B matching human gains at 918× lower cost per percentage point (Northcutt et al. (2026)).
- **Prompt-based micro-personalization of an LLM tutor (2026):** Basu, Kakar & Goel (2026) personalize the Jill Watson Large Language Models (LLMs)/RAG (Retrieval-Augmented Generation) teaching assistant at the level of individual questions entirely through prompt engineering — conditioning responses on six learner dimensions (metacognitive Self-Assessment, abstraction, verbosity, perception, processing, understanding) and classifying each query's cognitive demand with a Bloom's Taxonomy classifier, yielding 96 learner profiles with no model retraining. NLP analysis of 2,910 responses and a human study found measurable, perceptible differences in response abstraction, verbosity, complexity, and processing style aligned with intended effects. It demonstrates response-form (rather than content) adaptation as a scalable, modular route to adaptive behavior in a deployed tutor.

Key ITS concepts

- **Knowledge Tracing** — modeling what a student knows over time (Bayesian, deep learning, IRT-based)
- **Cognitive Diagnosis** — fine-grained assessment of which knowledge components and Misconceptions about AI a learner holds; the assessment-side counterpart to Knowledge Tracing that feeds the tutor's pedagogical decision
- **Learner Modeling and Adaptive Instruction** — broader learner representation including affect, engagement, and misconceptions
- **Adaptive Learning** — systems that personalize content sequencing based on learner state
- **Scaffolding** — providing just enough support to enable progress without giving away answers
- **productive struggle** — letting students wrestle with difficulty rather than over-helping
- **feedback loops** — ITS feedback cycles that diagnose, guide, and verify

Historical context

The ITS field has produced landmark systems (Cognitive Tutors, Andes, AutoTutor) and continues to evolve. The Zerkouk et al. comprehensive ITS review catalogs this evolution. The tension between structured ITS

and open-ended LLM tutoring is explored in the correct answer trap research and rethinking scaffolding for LLM tutors.

AI tutoring with LLMs: practical guidance

For instructors deploying AI tutors and developers building them, the knowledge base's findings translate into concrete practice:

Evaluate tutors on whether they teach, not just solve. A model that tops a solving leaderboard is not necessarily a good tutor — task-solving ability and learning-supportive behavior correlate only partially ($r \approx 0.42$), and several models shift rank when scored on pedagogy. Report and scrutinize **solving and pedagogy scores separately**, and prioritize tutors that score on guiding questions, calibrated hints, and non-disclosive scaffolding over those that produce fast answers.(Measuring Whether LLM Tutors Teach or Solve: A Diagnostic for Educational Impact)(Methodologies for improving the quality of AI tutoring in K-12 education)

- **Pedagogical quality is a floor, not proof of learning.** A structured audit of 88 LLM-tutoring studies coding the field as a five-stage loop — learner-state inference, pedagogical action, tutor training, evaluation, student simulation — finds pedagogical evaluation widespread (77/88) but human learning gains in only 10 studies and transfer or delayed retention in one (Adak et al. (2026)).
- **A large multi-discipline randomized trial found adverse effects from a well-grounded tutor.** Liu et al. (2026) randomized 2,379 undergraduates and 30 instructors across 13 blocks and 11 of one U.S. public university's 12 schools to access to a GPT-4o tutor with retrieval over each instructor's own course materials, embedded in the LMS with citations to slides and lecture-video timestamps. In the exact-match sample — sections of the same course — access reduced final grades by 4.12 points (0.37 SDs) and GPA-scale letter grades by 0.13 SDs, while the full sample showed no significant achievement effect; engagement fell in both samples (recorded participations −0.90 SDs, active days −0.51 to −0.61 SDs). Only about 15% of treated students used the tool and users averaged roughly four sessions, yet classroom-level behavioral differences were large, and 73.8% of 3,460 classified requests were direct-answer requests rather than practice or feedback on the student's own attempt. The authors read it as a technical-versus-instructional integration gap: no treatment-group instructor reported integrating the tool into assignments and most left it in the default direct-instruction mode, so course grounding and convenient access did not produce productive use.

Design for pedagogical structure, not frequency. The educational payoff of AI tutoring depends on *how* the tool is used and designed, not on how often it is used. Instructor-designed tutors scoped to course objectives, learner proficiency, and a curated knowledge base outperform unstructured general-purpose chatbot use.(Instructor-Designed AI Tutors in University Foreign Language Education: A Mixed-Methods Study of Learner Motivation and Reflective Learning Experience Based on Self-Determination Theory) A preregistered randomized field experiment tested that claim against the realistic alternative rather than an AI-free baseline: 86 students in an online-MBA corporate-finance module were assigned to a tutor grounded in the module's own lectures, readings and problem sets or to a holdout that kept standard resources with consumer AI freely available, and tutored students gained 6.63 more points of 55 (95% CI [+1.95, +11.31], p

= .007) while the share of short written answers at relational quality or better rose from 8% to 49% against 8% to 27%. Channel was the null margin — voice nearly doubled interaction density and cost 2.8× more to deliver, yet weekly mastery differed by −0.01 points of 11 (p = .98) — which makes delivery format an adoption and engagement lever rather than a learning technology. The holdout did not close the gap either: the nine students reporting external-AI use gained no more than the eight reporting none (+10.3 versus +12.8 of 55, p = .45).

Use iterative live evaluation to keep improving. Because LLMs are opaque, treat evaluation as the engine of improvement: instrument a small set of quality and engagement metrics, run live experiments on models, prompting, personalization, and agents, and let data drive changes — the same discipline Khan Academy applies to its K-12 tutor (Khanmigo).(Methodologies for improving the quality of AI tutoring in K-12 education)

Support the learner's autonomy, competence, and relatedness. AI tutors work best when they feel like a safe, structured practice space rather than an answer machine. Provide immediate, nonjudgmental Feedback; scope the tutor to the learner's level so competence is achievable; and preserve learner agency by keeping the tutor a complement to (not a substitute for) other instruction.(Instructor-Designed AI Tutors in University Foreign Language Education: A Mixed-Methods Study of Learner Motivation and Reflective Learning Experience Based on Self-Determination Theory)

Guard against answer disclosure. The central failure mode of LLM tutoring is giving the answer away, which inflates immediate performance while undermining durable learning. Use Socratic prompting, calibrated hints, and non-disclosive scaffolding — and measure outcomes on unassisted, transfer tasks, not just in-tool performance.(Measuring Whether LLM Tutors Teach or Solve: A Diagnostic for Educational Impact)(Socratic Method)

- **Numbering-only references defeat retrieval.** In a bilingual RAG tutor for a 400-student data science course, posts citing "P2 Q10" retrieved poorly until an extraction stage rewrote them as standalone questions, after which 97.46% of programming references resolved (Shen et al. (2026)).
- **A visual channel shifts tutoring toward checking work, and proactivity toward repair.** With a phone camera on the page, correctness feedback rose from 40% of tutor messages to 63-69% and error identification from 20-22% to 41%, while a proactive tutor that waited after 96% of 5,047 paper analyses was rated supportive (5.53 of 7) rather than interrupting (2.45) (Kotalwar et al. (2026)).

Separate diagnosis from feedback. LLM tutors reliably confirm correct steps but over-reject valid-but-suboptimal reasoning and over-validate incorrect solutions — and accurate diagnosis does not reliably yield actionable feedback.(Confirming Correct, Missing the Rest: LLM Tutoring Agents Struggle Where Feedback Matters Most) The coupling also cuts the other way: Reddig et al. (2025) found GPT-4 still crafted relevant, general-but-correct feedback ~74% of the time even after misdiagnosing an error (by restating the concept or expected answer format), yet almost all factually incorrect feedback followed a wrong diagnosis — so error identification remains the crux of actionable tutoring. A hybrid architecture works best: let a knowledge-grounded classifier handle solution diagnosis while the LLM focuses on open-ended scaffolding and dialogue. - **Fairness auditing is becoming part of tutor evaluation.** EduFair-Bench holds the simulated student fixed and varies only demographic attributes, showing that tutoring quality is not uniform across

learners and that reward-tuning pedagogy does not automatically remove those differences (EduFair-Bench: Evaluating Pedagogical Fairness of LLM Tutors Across Student Demographics).

- **More scaffolding and more context are not automatically better.** A 2×2 randomized trial with 132 introductory Python students compared four GPT-4o teaching assistants differing only in system prompt and supplied context, and the Socratic assistant with full problem context - the configuration closest to pedagogical intuition - was rated significantly less supportive of task completion (mean rank 48.63, $\mu = 3.53$) than the other three ($\chi^2(3) = 12.14$, $p = .007$). Socratic conditions sent more queries ($\mu = 11.1$ per problem without context) while no-context students wrote longer messages, doing the contextual work themselves, and the lowest share of full-comprehension post-task explanations (48%) and the highest external-LLM use (23%) also fell in the Socratic + Full Context condition (Eastwood et al. 2026).

AI tutoring as a spectrum of relational intensity

A unifying lens from the Stanford SCALE / NSSA brief (Turano et al. 2026) reframes AI tutoring as **not a monolith but a spectrum** defined by *relational intensity* — the depth and consistency of the human connection between student and tutor. The brief maps models from fully human-led tutoring (in-person or remote), through **human-led with AI support** (AI assists the tutor behind the scenes) and **AI-led with human support** (a human oversees and intervenes), to **AI-only tutoring** (no direct human oversight). The central finding: as direct human relationships decrease, the evidence base becomes thinner, and unresolved questions accumulate about student safety, developmental impact, and long-term efficacy.

- **AI augments, does not replace, high-impact tutoring.** The brief's core message is that AI is best used to *enhance tutor effectiveness and educator capacity* within high-impact tutoring (regular school-day sessions, small-group ratios ≤ 1:4, well-trained consistent tutors, data-driven instruction, vetted materials, strong student-tutor relationships) — not to substitute for the human-led relationship that drives learning gains. This aligns with the knowledge base's broader finding that pedagogically designed AI tutors outperform general-purpose chatbots (Stanford evidence base, umbrella review).
- **Dosage, not model capability, is the binding constraint.** The brief reports that AI-led tutoring inherits the dosage evidence base (~90 minutes weekly) only when scheduled, supervised, and protected within the school day; in a study of 181,000 students on a supplemental math platform, only 5% reached the recommended minutes and 41% never logged on, with teacher/school/district factors explaining 57% of usage variance. This converges with the field-experiment evidence above (Khanmigo, NUMI) that engagement and integration, not raw capability, determine whether AI tutoring helps.
- **Human oversight improves engagement and alignment but not dosage.** The brief's RCTs found human check-ins raised elementary students' engagement with an AI platform but did not reach the dosage associated with gains nor improve reading achievement. The practical implication: schedule and supervise AI tutoring on the same terms as human-led tutoring, and design for enforcement of engagement — the opt-in requirement an on-device AI tutor reintroduces is exactly what live school-day tutoring eliminates.

- **The relationship is the irreducible element.** The brief emphasizes that AI does not yet replicate human relationships, and that relationship-building (especially consistent tutor-student pairings) improves engagement, attendance, motivation, and outcomes. Developers describe using AI's strengths rather than replacing relationships — a design stance echoed in SafeTutors and affective tutoring research.
- **Safety and privacy are non-negotiable guardrails.** For direct-to-student AI, the brief calls for strict student data privacy safeguards, Guardrails on student safety, and attention to the depth of unmonitored interaction — open questions remain about AI companions' effects on developing minds and prosocial development.

This relational-intensity framing is the "not a monolith" counterpoint to the field: evaluating any AI tutor should begin by asking *which conditions of effective tutoring it reproduces, changes, or drops* — rather than asking whether "AI tutoring works" in the abstract. The brief's human-led baseline can also be absent entirely: a six-week pre-test/post-test study across three Kwara State colleges of education gave 240 technical-education students a localized tutor fine-tuned on Nigerian technical curricula and reported roughly double the practical-skill gain of 120 conventionally taught peers. Practicals there ran above 100:1 student-to-lecturer ratios with feedback delayed by days, so the authors' rationale was not augmentation but equitable *substitution* for scarce instructional staff — casting the tutor as a capacity subsidy for rural colleges rather than a complement to plentiful human tutoring. Two design choices carry the practitioner lesson: the tutor explains an error rather than only flagging it, and a "Clarify" feature restates technical terms in Yoruba or Nupe, adapting to the learner's language context rather than only their knowledge state; hints rather than answers and a safe-to-fail space are credited with the reported confidence increase in most of the AI-assisted group against fewer than half of controls. The evidence is indicative only — no effect sizes, an unnamed base model, self-reported confidence — but it marks the boundary the brief leaves open, the setting where AI is asked to stand in for absent instructional capacity. It ties the tutoring page to K-12 policy (Educational AI Policy), Privacy, Pedagogical Safety, and the human-in-the-loop concerns throughout (Impact of real-time AI feedback on the technical skill acquisition of STEM students in Colleges of Education in Kwara State).

Practical design and development guidance

Design for learning, not just performance. The strongest causal finding is that unguarded AI tutors raise assisted practice performance but *reduce* unassisted learning — the performance–learning gap. Guardrail against answer-copying by scaffolding **hints instead of answers** (require a student attempt before revealing output), and verify gains on unassisted, closed-book measures rather than in-tool performance.(Generative AI without guardrails can harm learning: Evidence from high school mathematics)(Distinguishing performance gains from learning when using generative AI)

Make hints genuinely productive, not bypassable. Classic hint designs can enable "button-through" strategies that skip learning. Prefer hints that reveal reasoning steps incrementally (Socratic prompting) over hints that directly supply the next answer, and preserve productive struggle rather than over-helping. (Revisiting the Hint Button: Consistent Negative Associations Between Unproductive Hint Use and Learning Outcomes in Intelligent Tutoring Systems)(Rethinking Scaffolding in LLM Tutors: The Interactional Mismatch Between Benchmarks and Real-World Deployments)

Keep the human in the loop. Let teachers author or curate the problem sets and misconception prompts the tutor draws on, and surface the tutor's reasoning so its decisions are auditable. Interpretable Knowledge Tracing and explicit, external didactic layers make LLM tutor behavior traceable and reproducible. (Interpretable Knowledge Tracing)(A didactical-driven teacher assistant for a dimensional modeling course)

Model the learner, not just the dialogue. Attach structured Learner Modeling and Adaptive Instruction and Knowledge Tracing components to LLM dialogue so the system can adapt difficulty and diagnose misconceptions from evidence rather than responding fluently but blindly — quality depends on both the base model and how it is adapted.(EduClaw-Bench: A Long-Horizon Benchmark for Pedagogical LLM Agents with Simulated Learners)

Yet off-the-shelf models may not supply that evidence: Worden et al. (2026) tested four frontier systems zero-shot against IRT ground truth on 2,548 mathematics items and found knowledge tracing barely beat a 51.3 percent always-correct baseline, reaching only 56.2 percent at best.

Start from open tooling where possible. Open-source agentic tutoring frameworks (e.g. Deeptutor) lower the barrier to a citation-grounded, difficulty-calibrated tutor you can inspect and extend.(DeepTutor: Towards Agentic Personalized Tutoring)

Audit the knowledge-component model against learning curves, then redesign from what the data shows. A classroom crossover study applied Huang et al.'s data-driven redesign process to four units of a middle-school mathematics ITS chosen by topic, not redesign suitability. Learning-curve analysis in DataShop revealed an unmodeled interpolation skill and conflated sign-handling cases; splitting these KCs and adding focused practice with mastered-step skipping produced more productive time-on-task (38.9 vs. 31.6 active minutes, $p < .001$) and five additional skills mastered in the same class time — but no learning-gain difference. The null is explained by thin practice dose (below 70% AFM mastery in both conditions) and a post-test that lacked items on the newly split skill. Two lessons for developers: post-tests must cover newly discovered skills, and adaptive benefits are bounded by the practice students actually receive. (Evaluating a data-driven redesign process for intelligent tutoring systems)

Effective tutoring requires continual adaptation: Zhang et al. (2026) evaluate whether LM tutors adapt to learners' evolving understanding at teacher-annotated decision points. They find frontier models default toward over-helpfulness and rarely push for rigor, and that evaluation-aware prompting improves but does not fully solve adaptivity. Each additional impasse turn lowered next-turn recovery odds by 12.7%, and questioning lost value with depth (scripted question × depth AOR = 0.78) while addressing the student's error grew more beneficial (AOR = 1.14) — a tutor's escalation, not just its answer-withholding, must change as an impasse persists (Ahtisham et al. (2026)). A systematic view of the RL-driven branch of this adaptation comes from Riedmann, Schaper & Lugrin (2025), whose review of 89 RL-in-education studies finds classical RL policies more consistently effective than Deep RL and RL adaptation delivering significant gains more often for guidance-related tasks (hints, Feedback) than for content scheduling — evidence that how an ITS adapts scaffolding matters as much as which algorithm it uses. - **Adapting the type of cognitive engagement, not just the intensity.** Tithi et al. (2026) held difficulty constant and varied the worked-example form — guided (active) or buggy (constructive) — via a BKT rule and a deep-RL policy, both beating random assignment (posttest 72.3 and 72.5 vs 65.7).

- **Deceptive overgeneralization (An et al. 2026)** shows ITS mastery stopping rules (BKT, 95% threshold) can end practice before learners learn *when to withhold* a skill: learners who

overgeneralized misapplied actions on first “do-not-act” items at 61.5%–100%, and targeted refrain-practice with constraint-naming Feedback reduced this to near-floor. Correctness-based mastery inference is necessary but not sufficient for ITS adaptivity.

- **Graph-based ITS for dynamic domains.** A graph-based intelligent tutoring system combines an Evolving Knowledge Space Graph with generative AI content creation and Bayesian knowledge propagation — which showed the highest knowledge gains — supporting adaptive learning in dynamic curricula.
- **Rule-integrated LLM tutoring for procedural domains.** Looi, Liu, and Sun (2026) tackle the inconsistency and pedagogical opacity of LLM tutors in primary mathematics through a design science study of a rule-guided system organized around a three-layer architecture — *diagnosis → intent selection → constrained response generation*. They formalize the distinction between **rule-guided scaffolding** (governed by auditable, replicable rules) and **ad-hoc scaffolding** (helpful moves difficult to audit or replicate). Evaluated via persona-based simulated dialogues and a classroom pilot with 40 Grade 5 students, rule-guided scaffolding improved interactional consistency, reduced premature answer-giving and early closure, and sustained cognitive engagement — while the classroom pilot surfaced interactional complexities, fragmented inputs, and attentional fluctuations that Simulation missed. This is a concrete blueprint for guardrailing Large Language Models (LLMs) tutors in well-defined procedural domains.
- **Multi-agent tutoring and automated assessment.** Multi-agent tutoring systems are being benchmarked with synthetic, trace-based evaluation. ASTRA supports alone-tutor, pair-tutor, and pair-multiagent configurations with socially differentiated agents, enabling reproducible analysis of interaction and participation balance in introductory programming. In parallel, context-aware prompting automates coding of collaborative problem-solving skills from process data, supporting large-scale tutoring assessment.
- **Design with the learner’s values, not just for learner performance.** Value Sensitive Design work with community college students and instructors in developmental math shows that the ethical dimensions of ITS are not separable add-ons: engaging students and instructors directly produced 16 value-aligned features spanning explainability (comprehension-check interpretation, learning-path connection, communicating the model’s confidence), learner control (control over re-assessment, review, pace, and AI-assistance level), and Privacy (data-repurposing control, permission prompts for sharing learning analytics and affective states). The study frames a persistent design tension — student agency vs. system-guided scaffolding — and notes that most institutions disable adaptive tutoring entirely, so value-informed design also depends on how (and whether) ITS AI capabilities are actually deployed.
- **Teachable agents and the classification of disengaged dialogue:** Rho et al. (2026) ran a GPT-4-Turbo teachable agent inside Math Nation (Algebra and Geometry), where students identified which of two worked solutions contained a misconception, justified the correction, and taught the agent — a Learning by Teaching structure with a separate mentor agent scoring explanation quality. Over 6,933 problems opened and 22,143 interactions logged, they built a six-category conversational-disengagement classifier (human-in-the-loop: 1,682 annotated utterances, fine-tuned LLaMA 3, weighted F1 = 0.910, model-vs-human $\kappa = 0.624$) and used it to study 246

middle-school students. The methodological contribution is as important as the finding: when a classifier labels most of the corpus, prevalence results must be stress-tested against the human-annotated subset — and here the headline association (False Answering and Mocking predicting higher post-test) evaporated under exactly that test.

Common Misconceptions

“A stronger model makes a better tutor.” Effectiveness hinges on pedagogical design — Scaffolding, feedback quality and the balance of autonomy and guidance — rather than on the underlying model. The clearest demonstration is the Apprentice Tutor College Algebra ITS: supplying GPT-4 with the tutor’s *interface structure* and Bayesian Knowledge Tracing skill estimates produced gains that the bare model did not, because the knowledge of how to teach lived in the system around the model.

“Training pedagogy into a model and prompting pedagogy at it are the same intervention.” They are distinct routes with distinct evidence. LearnLM mixed pedagogical data into Gemini’s post-training and was preferred by education experts over GPT-4o (**+31%**), Claude 3.5 Sonnet (**+11%**) and base Gemini. Prompt instructions are a cheap version of that; they do not reproduce a model whose disposition was shaped on pedagogical data.

“Intelligent tutoring was a pre-LLM technology that LLMs superseded.” The lineage is continuous and the ITS contribution is what the LLM era is still missing. ITS supplied the learner model, the interface constraints and the mastery estimates; modern systems that add an LLM to those components outperform the LLM alone, which makes the older discipline an ingredient rather than a predecessor.

“An AI tutor is a single kind of thing.” Tutoring spans a spectrum of relational intensity, from hint generation to sustained dialogue, and design conclusions from one point on that spectrum do not transfer to another. The pedagogical design question is therefore always “which kind of tutoring, doing what task” rather than “does AI tutoring work”.

Adaptive Learning

> **Adaptive learning** — AI-driven educational systems that adjust content, pacing, and instructional strategies based on individual learner characteristics and performance. Adaptive learning is the operational goal of much AI in education research: using student models to personalize instruction.

Questions to Consider

- 'Adaptive,' 'personalized,' 'individualized,' and 'customized' learning are often used interchangeably — but research suggests they are not the same. What do you assume each word means, and where might those assumptions be wrong?
- An adaptive system adjusts content and difficulty based on a model of what you know. What could go wrong if that model rests on shallow or unreliable signals about your learning?
- A key finding is that systems inferring mastery from correct answers can stop practice too early — before you learn when to withhold an action. Can you think of a skill where being 'correct' repeatedly still left you unprepared for a real situation?
- Over-adaptation can remove the productive struggle students need to learn deeply. If AI keeps making things easier the moment you struggle, what exactly does the learner lose?
- Meta-analysis suggests the adaptation mechanism — not the specific tool generation — drives learning gains. If the 'how' matters more than the 'which tool,' what should you look for when choosing adaptive software?
- LLM-based tutors can now adapt language and explanation style, not just difficulty. When does personalizing the way something is explained help learning, and when might it quietly undermine the learner's own agency?

Introduction

Core mechanisms

- **Measure-model-adapt loop:** Knowledge Tracing estimates what the student knows, Learner Modeling and Adaptive Instruction represents the learner, and the system adapts difficulty, content, and Feedback accordingly.
- **Personalization at scale:** Personalized Learning systems use adaptive algorithms to serve unique learning paths for each student. Deeptutor and elementary fraction tutors demonstrate adaptive personalization in practice.
- **Content sequencing:** Adaptive pretesting and lesson plan transformers optimize the order and type of content presented.
- **ITS integration:** Intelligent tutoring systems are the canonical adaptive learning platform, combining diagnosis with adaptation.
- **AutoML-driven profiling and diagnosis:** Traditional educational models struggle to process multi-source, heterogeneous learning-behavior data, which limits learner profiling and diagnostic

model development. A personalized neural cognitive architecture search framework driven by automated machine learning integrates multi-modal educational data with heterogeneous methods, generating diagnostic models tailored to heterogeneous learner profiles and supporting dynamic rather than static analysis of learning processes.

Effectiveness evidence

The knowledge base documents mixed evidence: adaptive systems improve outcomes when adaptation is grounded in reliable student models, but poorly-calibrated adaptation can harm learning. Personalization research distinguishes effective adaptation from superficial customization. Systematic reviews find that "adaptive," "personalized," "individualized," and "customized" learning are used inconsistently — so effect sizes depend heavily on how adaptation is operationalized, and the field calls for a unified framework.

A PRISMA 2020 review that screened 959 records down to 22 higher-education interventions counts adaptive pathways and recommender systems among the leading AI applications, but most studies improved existing practice rather than transforming it (AlSheikh et al. (2026)).

Pedagogical grounding, not technical capability, drives adaptation. A 15-year review of 127 intelligent tutoring studies finds most systems built around what the technology can do rather than a stated pedagogical principle, and puts the average ITS gain at roughly 20% against up to 98% for human tutoring (Zerkouk et al. (2025)).

Take-up, not the adaptation mechanism, was the binding constraint in a two-year district RCT: collapsing enrollment to a single step raised first-session take-up from about 45% to 83% on design changes alone, and intent-to-treat gains grew as take-up rose (Oreopoulos et al. (2026)).

A PRISMA-aligned review of 44 studies finds the engagement literature skewed toward behavioral engagement and thinnest on agentic engagement, and reports a novelty effect — engagement declining over time in longitudinal studies of ALEKS and W-Pal once the tool's novelty faded (Simon, Zeng & Fryer (2026)).

The AI era: LLM-based adaptation and its risks

Generative AI has expanded what adaptive systems can do — conversational agentic tutors, RAG (Retrieval-Augmented Generation)-grounded content, and Large Language Models (LLMs)-driven tutoring adapt not only problem difficulty but language and explanation style (e.g., LearnMate-2, Deeptutor, multi-agent adaptive tutoring). However, LLM-based adaptation introduces new risks: without reliable student models, adaptation may be based on shallow signals; over-adaptation can reduce the productive struggle students need (see Desirable Difficulties, Cognitive Offloading); and the balance between personalizing and preserving learner Learner Agency is an open design question (see agentic AI). A learner-requested variant of adaptation runs without any student model at all. In Sidorkin's (2026) graduate course the readings adjusted only when students asked follow-up questions to reframe, deepen, simplify or localize them, and comprehension-oriented requests reliably produced denser Scaffolding (3.4x to 8.7x more definitional markers than baseline text). Requiring at least three follow-up questions per reading turned the material into an interaction. It also relocates the adaptive burden onto the learner: adaptation here happens only if the student knows what to ask for.

Relationship to personalized learning and intelligent tutoring

Adaptive learning is frequently conflated with personalized learning, but they differ. **Adaptive learning** is the *mechanism* — real-time adjustment of content, pacing, and difficulty based on a learner model. **Personalized learning** is the *broader goal* of tailoring the whole learning experience to an individual, of which real-time adaptation is one implementation. Adaptive systems are the canonical *means* toward personalization. Intelligent tutoring is the classic *platform*: ITS combine diagnosis (student modeling, knowledge tracing) with adaptation, and LLM-based tutors adapt conversationally. Together with personalized learning, adaptive learning is an application-side member of the learner modeling and adaptive instruction family — consuming the learner representations that student modeling, Knowledge Tracing, and Cognitive Diagnosis produce.

Research evidence

- **Meta-analytic evidence on adaptive + AI tools.** A World Bank meta-analysis of 14 RCTs pools adaptive computer-assisted learning, intelligent tutoring, and generative AI on a common scale, estimating an average learning gain of ~0.125 sd with no significant difference between the two technology generations — evidence that the adaptation mechanism, not the specific tool generation, drives gains.
- **Interpretable rating plus time-budgeted routing.** Sahu et al. (2026) keep a few explicit learner scalars — rating sensitivity, response quality and momentum — and route questions under a time budget, cutting rating-update volatility roughly in half against fixed Elo while trailing neural knowledge tracing on prediction (AUC 0.7532 against GKT's 0.8658).
- **Adaptive algorithms compared in dynamic domains.** Graph-based ITS research compares multiple adaptive learning algorithms (including Bayesian knowledge propagation and intuitionistic fuzzy logic) in a graph-based knowledge representation framework for dynamic curricula.
- **RL as an adaptation mechanism, empirically mapped.** Riedmann, Schaper & Lugrin (2025) synthesize 89 RL-in-education studies and find adaptation splits into content-related (instructional sequencing/content scheduling, n = 53) and guidance-related (hints, Feedback, activity selection, n = 36) mechanisms — with RL showing statistically significant superiority over baselines more often for guidance-related adaptation than for content scheduling. They recommend model-free RL for adaptive learning and caution that classical RL outperformed Deep RL in the reviewed studies.
- **Correctness-based adaptivity can stop practice too early.** An, McLaren, and Stamper (2026) found that adaptive systems inferring mastery from correctness risk terminating practice before learners encounter contexts where the learned action should be withheld — leaving deceptive overgeneralization undetected. They recommend including "do-not-act" detector tasks before mastery stopping rules trigger, so adaptation tests conditional understanding (knowing when to withhold an action), not only correctness.
- **A mastery streak is not durable learning.** In a 6,000-student middle-school field experiment, an AI-supported three-correct-in-a-row mastery rule raised platform-defined attainment by roughly

28.7 percentage points without improving a delayed test a week later, so mastery metrics need validating against delayed learning rather than standing in for it (Oreopoulos et al. (2026)).

- **Adapt the *type* of cognitive engagement, not only the difficulty.** Tithi et al. (2026) found BKT and deep-RL policies assigning guided (active) or buggy (constructive) worked examples both beat random assignment in a 113-student logic tutor (posttest 72.3 and 72.5 vs 65.7), with BKT serving low Prior Knowledge students best and DRL the high.
- **More feedback is not better feedback.** In an eight-week adaptive stochastics course (194 students), directive, informative and transformative feedback were taken up differently, and transformative feedback was associated with cognitive overload rather than better regulation — adaptivity has to match the learner's phase and need, not maximize feedback density (Mejeh & Fromm (2026)).
- **A profile is not a trait.** Strategy scores varied mainly by context rather than by student, with a mean intraclass correlation of 0.14 across 234 primary-school learners, and 74.6% of high-coordination-demand failures looped straight back into another failure without intervention (Geoffre, Yuan and Geoffre (2026)). Adaptation built on a stable learner type discards most of the signal; reading the state a learner is in does not.
- **Engagement profiles as adaptation targets.** An, Hammock & Goel (2025) traced 315 online learners building 822 models in VERA and classified their engagement into Observation, Construction, and Exploration profiles, finding that learners tend to progress from construction-focused behavior toward fuller, hypothesis-driven Exploration while Observation persists across phases. They argue adaptive and personalized design should recognize these profiles and target feedback (e.g., recommending similar models or supporting deeper conceptual understanding) to move surface-level observers toward more integrative, full-cycle modeling.
- **A memory that is read but not written is not adaptation.** CoLearn's frozen-memory control served fixed items while still reading the learner profile, and the share of items aimed at a genuinely weak skill fell from 0.72 to 0.57, with final mastery error rising above the adaptive condition (He et al. (2026)).
- **The gain came from sequencing, not from a smarter tutor.** Chung et al. (2026) trained a personalized tutor with LLM-guided reinforcement learning and deployed it in a five-month Python course across ten Taipei high schools, randomizing 770 students between adaptive and fixed easy-to-hard problem sequences. Adaptive sequencing raised the in-person, unassisted final exam score by 0.156 SD (0.150 SD with controls) — while mediation analysis attributed the effect almost entirely to engagement (0.185 SD via time on task, 0.149 SD via attempts) rather than to easier or harder material, and gains were largest for beginners and lower-tier schools. The adaptive lever was the order of practice, not the quality of the chat.
- **Keep mastery decisions rule-based and confine machine learning to monitoring.** An eight-week adaptive STEM program for 30 sixth-graders governed pathways by rule-based mastery while machine learning tracked performance, keeping adaptation auditable, but with no pretest and one classroom per condition, its gains are a pilot template to validate locally (Bin Bakheet et al., 2026).

- **Adapt the bottleneck attribute, not the weak average.** Transition modeling of knowledge states ranked analytical thinking as the hardest to acquire and the easiest to lose — lowest forward transition probability 0.31 and highest backward 0.22-0.23 — making re-practice of the flagged attribute a sharper adaptation target than overall mastery (Feng & Huang, 2026).
- **Adaptation from process sequences, not aggregate scores.** Wong, Bulathwela & Cukurova (2026) derived scaffold rules by mining the *order* of 65 students' dialogue turns in triads, moving adaptive learning from aggregated behavioral or performance measures toward individual process sequences; maximal scaffolding raised on-task behavior but also scripting, and the design is untested.

Common Misconceptions

- **"Adaptive means personalized means individualized."** Systematic reviews find these four terms used **inconsistently across the literature**, which means reported effect sizes depend heavily on how adaptation was operationalized rather than on adaptation itself. A meta-analysis pooling studies that used the words differently is pooling different treatments, and the average describes none of them.
- **"Mastery reached in the system is mastery learned."** In a **6,000-student middle-school field experiment**, an AI-supported three-correct-in-a-row mastery rule raised **platform-defined attainment by roughly 28.7 percentage points without improving** a transfer measure. The rule optimized the platform's own criterion. This is the clearest available demonstration that a mastery signal is a model of learning, not learning.
- **"Correctness-based adaptivity knows when to stop."** An, McLaren, and Stamper (2026) found systems inferring mastery from correctness risk **terminating practice too early** — the system reads a correct run as understanding and withdraws the practice the learner still needed. Adaptivity that stops on success can subtract exactly the trials that produce retention.
- **"The bottleneck is how good the adaptation is."** In a **two-year district RCT**, the binding constraint was **take-up**: collapsing enrollment to a single step raised first-session take-up from about **45% to 83%** on design changes alone, and intent-to-treat gains grew accordingly. The cleverest adaptation serves nobody who never reaches it.
- **"Engagement persists once established."** A PRISMA-aligned review of **44 studies** found the engagement literature skewed toward behavioral engagement and thinnest on agentic engagement, and reports a **novelty effect** — engagement declining over time in longitudinal studies of ALEX and similar systems. Early engagement is not a stable property of the design.

What this means for practice

For instructors and designers

- Define mastery by what you need to be true, not by what the platform can see. The 28.7-point attainment gain with no transfer improvement is the failure mode to design against: if the criterion is three in a row, three in a row is what you will get.

- Keep practice going past the correctness signal for anything you need retained. Use spaced and interleaved review rather than trusting an adaptive system to decide when a learner is done.
- Remove enrollment friction before tuning the algorithm. 45% → 83% take-up from collapsing a step outperformed most pedagogical improvements in this literature.
- Plan for engagement decay. Longitudinal work documents decline; a design that depends on sustained voluntary use needs a reason to keep being used.
- Check which construct a system claims to adapt on. Behavioral engagement is the most studied and the least informative about learning; agentic engagement is thinnest in the evidence base.

For developers

- Report the operational definition of "adaptive" alongside any effect size you cite, because the literature's definitions diverge and pooled numbers inherit that ambiguity.
- Distinguish your mastery criterion from learning outcomes in your own validation. If your validation measure is the same signal that drives the adaptation, it is not independent evidence.

Personalized Learning

> **Personalized learning** — tailoring educational experiences to individual learner profiles, including prior knowledge, learning pace, preferences, and affective states. AI enables personalization at scale, though the gap between *system personalization* and *learner-perceived personalization* remains an open measurement challenge. Alongside adaptive learning and intelligent tutoring, it is one of the application-side members of the learner modeling and adaptive instruction family — consuming learner models to adapt instruction.

Questions to Consider

- When you think of 'personalized learning,' do you imagine content tailored to a learner's pace, or to their chosen goals? The page says these are deeply different (uniform outcomes via varied paths vs. diverse outcomes). Which do you value more, and why?
- The page distinguishes personalized learning (the goal) from adaptive learning (one mechanism). Can you think of personalization that doesn't involve real-time adaptation—and does it still count?
- A system can adapt without the learner ever feeling recognized. When have you experienced being 'personalized to' without feeling genuinely known? What's the difference?
- The page flags that over-personalization can strand learners in low-expectation tracks. How might well-intentioned AI tailoring accidentally lower the ceiling for a learner?
- Personalization needs detailed learner data; privacy needs data minimization. Where do you draw the line between 'enough data to adapt' and 'so much that the learner is exposed'?
- What would an AI need to remember about you across sessions to genuinely personalize your learning—and what are the risks of it remembering those things?

Introduction

Tailoring educational experiences to individual learner profiles, including prior knowledge, learning pace, preferences, and affective states. AI enables personalization at scale, though the gap between *system personalization* and *learner-perceived personalization* remains an open measurement challenge.

- **Mishra et al.** distinguish two forms of personalization with deep historical roots — uniform outcomes reached via varied paths (Skinner's teaching machines to Khan Academy-style mastery tutoring) vs. diverse, learner-chosen outcomes — mapping onto the field's control-vs-agency tension.
- **Personalization can be met by generating the material rather than finding it.** DagFlow-AI generates synthetic statistics datasets matched to a student's stated interest, the course learning objectives and the intended skill level, a three-way match the authors argue real datasets rarely satisfy (Arthur et al., 2026). The limit is built in: synthetic data cannot teach data collection, measurement or study design, so the tool complements real data rather than replacing it.

Architectures for AI-Driven Personalization

Longitudinal Memory (PersonaVLM → Education)

Nie et al. (2026) developed a Multimodal AI long-term memory architecture (PersonaVLM) that maintains persona consistency across interactions. Mapped to education, this enables tutoring systems that remember a learner's Misconceptions about AI, preferred explanations, and progress history across sessions—addressing a critical deficit in stateless chatbot tutors.

Agent-Native Personalization Substrate (DeepTutor)

Zhao et al. (2026) design every feature of DeepTutor to share a common personalization substrate, rather than bolting personalization onto reactive tools. This architecture ensures cross-modality coherence: the same learner profile drives problem solving, question generation, and collaborative writing.

Multi-Agent Social Personalization (MAIC)

Yu et al. (2024) personalize not only content but *social context*. Classmate archetypes (Class Clown, Deep Thinker, Note Taker, Inquisitive Mind) create varied peer-learning dynamics matched to individual learner needs.

AutoML for Learner Portraits

Personalization is a central objective for improving educational quality, yet processing multi-source heterogeneous learning-behavior data remains a challenge. A personalized neural cognitive architecture search framework, driven by automated machine learning, builds learner portraits and generates diagnostic models for heterogeneous learner profiles, integrating multi-modal data to move beyond static examination outcomes.

A static knowledge base cannot personalize: ontologies evolve slowly and handle uncertainty poorly, so the architecture matches representation to knowledge type — declarative to ontologies, procedural to rules, uncertain to fuzzy or probabilistic ontologies, implicit to analytics and machine learning — and prefers a system of small mapped ontologies to one monolithic model (Ivanova, 2026).

Relationship to adaptive learning and intelligent tutoring

Personalized learning is often conflated with adaptive learning, but they are not the same. **Adaptive learning** refers to the *mechanism* — a system adjusting content, pacing, and difficulty in real time based on a learner model. **Personalized learning** is the *broader goal* — tailoring the full learning experience (content, pathways, pacing, preferences, goals) to an individual, of which real-time adaptation is one implementation. Adaptive systems are a *means* toward personalization, but personalization can also be achieved through static learner profiles, choice-based pathways, or human-tutor tailoring that does not adapt in real time.

A PRISMA 2020 review of 22 higher-education interventions places personalized-learning support and adaptive pathways among the dominant AI use cases, yet most implementations improved existing practice rather than transforming it (AlSheikh et al. (2026)).

Intelligent tutoring sits in between: ITS are the canonical *adaptive* platforms that deliver personalized instruction through structured student modeling, while Large Language Models (LLMs)-based tutors personalize conversationally. All three are the application-side members of the learner modeling and adaptive instruction family — they consume the learner representations produced by student modeling, Knowledge Tracing, and Cognitive Diagnosis to decide what to teach next. The distinction matters for evaluation: studies that label a system "adaptive," "personalized," or "individualized" interchangeably (see below) can obscure whether the claimed benefit comes from real-time adaptation, learner choice, or content tailoring.

Measurement Challenges

- **System vs. perceived personalization** — A system can adapt without the learner feeling recognized
- **Longitudinal validity** — Personalization benefits may decay if profiles become stale or overfit
- **Equity risks** — Over-personalization can strand learners in low-expectation tracks
- **Bias risks** — Conditioning on student attributes can encode stereotype: with essays held constant, feedback for students marked by race, language, or disability became more praising and less critical (Tan, Phalen & Demszky (2026)).

Personalization and assessment

Personalization and Assessment are tightly coupled in AI-driven learning. Adaptive personalization depends on ongoing formative measurement of what a learner knows (via Knowledge Tracing, Learner Modeling and Adaptive Instruction, and Cognitive Diagnosis) to decide what to adapt next — so the reliability of the Assessment signal directly constrains the quality of personalization. Conversely, when summative assessment is personalized per-learner, fairness and comparability become harder to establish. The knowledge base's research warns against over-adapting to shallow or noisy signals: adaptive systems that mis-measure a learner can personalize in ways that reduce learning rather than support it, and AI-native students whose Self-Assessment is unreliable (an "absent cognitive baseline") are harder to model accurately.

Personalization in the AI era

The strongest evidence that this concern is not hypothetical comes from a three-wave longitudinal study of 486 Chinese undergraduates (Li, Lin & Qiu, 2026). It found that the more personalized students perceived their AI-adaptive environment to be, the *lower* their self-regulated learning. The study names this the "personalization paradox." Shifts in academic emotions carried most of the effect: encountering the adaptive environment predicted less enjoyment and more anxiety and boredom, and those emotional changes together accounted for roughly half of the association between personalization and reduced self-regulation. AI literacy buffered the damage, weakening the negative emotional association to non-significance at high literacy. Personalization therefore appears to buy adaptive fit at a cost to the learner's own regulatory activity, and the study points to emotional experience — not only cognitive load — as the channel through which that cost is paid.

Where the diagnosis behind a path is validated, personalization pays off by lowering load rather than by covering more: shortest-path remediation averaged 3.82 steps and cut study time 22.0% (57.6 versus 73.8 minutes), with cognitive load carrying 53.7% of the post-test effect (Feng & Huang, 2026).

Evidence for the tool can itself be negative at small scale: in a five-day elementary fraction trial (final n = 22), the business-as-usual group showed significantly greater comprehension gains than the AI-adaptive Mathbot group, and the authors flag grade-level confounds, guessing and licensing cost as limits — an "adaptive" label carries no effect (Holman (2024)).

Reinforcement learning is a distinct mechanism for personalization, and Riedmann, Schaper & Lugrin (2025) map its empirical track record: their PRISMA review of 89 RL-in-education studies finds RL personalization concentrated in Higher Education and Math Education, with adaptation implemented mainly as content scheduling (n = 53) or guidance-related personalization such as hints and feedback (n = 36). They report that RL policies beat non-adaptive baselines most often on guidance-related adaptation and on affective variables (63% of tested studies), and that learning gain — especially normalized learning gain — was the most effective reward source — practical guidance for designing reward signals that personalize toward genuine learning rather than engagement.

Wang et al. (2026) show the reward objective is itself a personalization choice: an RL coach trained on the learner's independent competence cut lap time 27.9% ($p = 0.005$) where rule-based fading produced no reliable change, and the authors argue coding agents optimized for task performance carry no incentive for what the human retains.

Bernstein and Sibia (2026) sharpen a distinction between interest personalization and expertise personalization: interest-matched GenAI analogies were reported as more engaging and memorable but not uniformly more trusted, and some students preferred the generic technical explanation even when the analogy matched their stated interest, for self-sufficiency and completeness (Flawed but Memorable: Student Critical Reception of Interest-Personalized GenAI Analogies in Computing Education). Their design recommendation is to personalize through source-domain structure and to ask students what they already know, not only what interests them, since familiarity with a source domain is what lets a learner inspect the analogy. They also recommend giving learners control over personalization through a menu of analogies, opt-in, or offering generic and personalized versions together. Sidorkin (2026) documents a further pairing at the level of course materials rather than individual explanations: weekly readings generated on demand for a graduate educational leadership course were tailored at once along interest (sector, professional role, local examples) and comprehension level (pacing, definitions, depth). The resulting logs shared a common backbone (TF-IDF cosine similarity of 0.50 to 0.61), which he reads as a template with adjustable dials rather than a wholesale rewrite per learner. The same corpus shows that tailoring was structural but uneven in intensity: artifact-level tailoring markers averaged 52.24 per 10,000 words and ranged from 38.74 to 74.29 across logs, while comprehension-oriented prompts produced 3.4x to 8.7x more definitional Scaffolding than baseline explanatory text.

A third axis of personalization is the *goal*, and it is the input AI planners handle worst. Liu et al. (2026) paired 2,000 synthetic learner personas with a 347-textbook, 4,092-concept prerequisite graph and asked ten LLMs to plan, step by step, which knowledge a learner should study to reach a stated target unit. The models produced structurally sound curricula — DeepSeek-V3.1 reached 90.9% on prerequisite-and-hallucination validity — while failing to adapt them to the learner. Adaptivity topped out at 44.7%, DeepSeek-V3.1's final

pass rate was 29.5% in Basic Education and 14.6% in Higher Education, and removing the mastery field from the persona cost up to 26.1 percentage points of adaptivity while leaving validity almost unchanged. Generating the whole path in one pass instead of interactively raised validity by as much as 30.8 points while cutting adaptivity by 28.8. The claim “personalized” is a claim about responding to a learner’s state, and the state variable is the part these planners can most easily do without — a computational counterpart to the measurement concern above.

A fourth axis is the *audience* rather than the individual learner: Bespoke regenerates an existing lecture for a named professional group (healthcare, finance, or energy), and its expert raters scored industry-framed versions 0.32 points higher on personalization depth (3.97 vs. 3.65) while audience calibration lagged (3.52). Tailoring to a cohort rather than to a learner is a cheaper and more tractable form of personalization, but the rubric that measured it assessed judged fit, not learner outcomes.

Personalization can outweigh a human presenter: in a large online course (493 respondents), students ranked AI-generated personalized videos above non-personalized human-recorded ones (mean rank 2.26 versus 2.69) and 88.4% ranked some personalized video first, against 73.8% for human-recorded (Tomlinson et al. (2026)).

How strong is the evidence

The only pooled estimate available here comes from a meta-analysis of four controlled studies covering 420 students, all in computing and engineering higher education (Govea Sotomayor & García Ortiz, 2026). The random-effects pooled effect is large, $g = 1.01$ (95% CI 0.33–1.68), and that number should be read as a caution rather than a headline. With four studies, the Hartung-Knapp adjustment widens the interval to −0.10 to 2.11 ($p = .063$), which includes no effect.

Heterogeneity is severe: $Q(3) = 25.20$, $I^2 = 88.8\%$, $\tau^2 = 0.41$. The 95% prediction interval, −0.42 to 2.43, means a new implementation could plausibly yield a null or negative result. Two of the four studies were at serious risk of bias and carried 53% of the weight. Publication bias was not assessable, because the usual tests need at least ten studies.

GRADE certainty was rated very low. The honest reading is that the point estimate is large and the interval is too uncertain to act on. The pooled outcome was academic performance in computing and engineering courses, not learning broadly. Claims that AI personalization works should carry that qualifier, since this is the thinnest base on which the page’s evidence rests.

Prompt-conditioned micro-personalization

Basu, Kakar & Goel (2026) show that the gap between system and perceived personalization can be addressed at the response level. Their framework for the Jill Watson Large Language Models (LLMs)/RAG (Retrieval-Augmented Generation) tutor combines learner-selected preferences (abstraction, verbosity, perception, processing, understanding) with system-inferred cognitive demand (Bloom’s Taxonomy) to produce 96 micro-profiles adapted at each interaction via structured prompt conditioning — no retraining, no domain-specific authoring. This is a hybrid of adaptability (learner-driven preference selection) and adaptivity (system-driven cognitive assessment), showing that personalization of *how* content is presented can be both scalable and perceptible to learners.

Terminological ambiguity

A recurring problem is that “personalized learning” is a broad, loosely defined umbrella term. Systematic reviews (Khalifeh et al., 2026) find that adaptive learning, individualized instruction, customized learning, and personalized learning are used interchangeably, with no universally accepted definition — a source of conceptual ambiguity that complicates research synthesis and evidence-based practice. The field increasingly calls for a unified framework and definition so that “personalized” denotes a precise, evidence-backed claim rather than a vague label (a point reinforced by the knowledge base’s critique of weak construct use).

Common Misconceptions

“Personalized learning and adaptive learning are the same thing.” Adaptive systems are one *means* toward personalization, not its definition. Personalization can equally be achieved through static learner profiles, choice-based pathways, or human-tutor tailoring that never adapts in real time. Treating the two as synonyms makes a school that offers rich learner choice but no adaptive engine look unpersonalized, and makes a tightly adaptive drill look more learner-centered than it is.

“Personalization pays off by covering more ground.” Where the diagnosis behind a path is actually validated, it pays off by *lowering load rather than by coverage*: shortest-path remediation averaged 3.82 steps and cut study time 22.0% (57.6 versus 73.8 minutes), with cognitive load carrying the effect. The benefit is fewer unnecessary steps, not more content per hour.

“A model that can generate a coherent curriculum can personalize it.” Generation and adaptation are different capabilities, and the gap between them is large. Curriculum generators were strong on prerequisite-and-hallucination validity — DeepSeek-V3.1 scored 90.9% — but weak on adapting to the learner: adaptivity peaked at 44.7%, and DeepSeek-V3.1’s final pass rate fell to 29.5% in the Basic condition. Prerequisite validity is not personalization.

“Generating the material removes the constraint real content imposes.” Generation relaxes one constraint and cannot relax others. DagFlow-AI generates synthetic statistics datasets matched to a student’s stated interest, the course objectives and the intended skill level — a three-way match real datasets rarely satisfy — but its authors state the limit plainly: synthetic data cannot teach data collection, measurement or study design, so the tool complements real data rather than replacing it.

“Reported learning gains are what validate these systems.” In the RL and personalization studies surveyed here, policies beat non-adaptive baselines most often on guidance-related adaptation and on affective variables (63% of tested studies), while learning gain — especially normalized learning gain — was the *least* commonly reported outcome. A literature that reports engagement and affect far more than learning is not evidence that learning dominates.

Implications for Practice

For instructors

- Ask what is being adapted before believing the word “personalized”: the content, the sequence, the pace, the affect, or the presentation. Different adaptations carry different evidence, and only some have learning outcomes attached.

- Prefer systems that shorten the path over systems that add content. The measured benefit in the remediation study was 22% less study time, not more coverage.
- Keep the parts of the discipline a generated dataset cannot supply — data collection, measurement, study design — as real work, and let personalization operate on the practice around them.

For developers

- Report learning outcomes, not only engagement and affect. The survey finding that learning gain is the least-reported measure is a description of what the field is currently shipping, not a template to copy.
- Distinguish generation quality from adaptation quality in your own evaluation, ideally reporting both separately, because strong prerequisite validity can coexist with adaptivity under 50%.
- Treat the reward objective as a personalization choice in its own right: an RL coach trained on the learner's independent competence cut lap time 27.9% ($p = 0.005$) where rule-based fading produced no reliable change.

For researchers

- Stop conflating personalization with adaptation in the constructs you measure, and say explicitly which mechanism produced the effect.
- Report normalized learning gain as a primary outcome; its scarcity in the literature is a gap to close rather than a convention to inherit.

Recommender Systems and Learning Paths

> **Recommender systems and learning paths** — the part of adaptive and Personalized Learning technology that decides *what a learner should encounter next* and in what order: which resource, practice item, or course to rank toward them, and which sequence of concepts to walk through. Its two method families are behavioral — collaborative filtering over interaction logs — and semantic — sequencing over a knowledge graph of concepts, resources, and prerequisite relations — increasingly fused into hybrid models. Because the output is a ranked list rather than a dialogue, the distinctive problems are selectivity and legitimacy: cold start and popularity bias under sparse data, the directional asymmetry of prerequisites, and whether a teacher or learner can understand, audit, and trust the list they are shown.

Questions to Consider

- A recommender learns from what learners clicked, watched, and completed. If the system only sees behavior, whose learning is it actually modeling — and what does it miss for a student who is quiet, struggling, or already knows the material?
- In one study, teachers found curricular-language explanations more understandable and trustworthy than feature-importance charts. What would an explanation of a recommendation have to say before *you* would act on it?
- Prerequisite relations run in one direction only — knowing B does not imply knowing A. Why might a model that scores concept pairs independently get this wrong, and what would go wrong downstream for a learner if it did?
- Path optimization studies report shorter paths and better post-test scores, with reduced cognitive load as the main mediator. Is a shorter path always the better path, or can efficiency remove practice a learner needed?
- An audit of an educational recommender found popular materials still dominated lists after fairness and diversity interventions. If popularity keeps winning, what would make you redesign the objective rather than tune the reranker?
- Learning Design data from 554 courses showed Acquisition (knowledge transmission) as both the most common activity type and the most common entry point. If AI recommends “what comes next” from that data, whose design habits does it reproduce?

Introduction

Educational recommender systems exist because the supply of learning material has outgrown any human’s ability to navigate it. Introductory programming alone has many thousands of practice activities, and organizing them into instructionally meaningful bundles normally requires time-intensive expert curation. A recommender takes a learner’s history, the properties of the material, or both, and produces a ranked shortlist or an ordered path through content.

Where Adaptive Learning describes the mechanism of adjusting content, pacing, and difficulty to a learner model, and Intelligent Tutoring describes the platform that does so in dialogue, recommender research concentrates on the *selection and sequence decision* itself: the ranking function, the structure it ranks over, and the evidence it uses. That decision layer brings its own failure modes, taken up in the sections below.

How Educational Recommenders Work

Behavioral recommenders inherit the logic of collaborative filtering: learners with similar histories are assumed to want similar resources, so the system predicts from co-occurrence rather than content. This is powerful where data are dense and brittle where they are not. Evangelista and Bukhari (2026) state the problem plainly — accuracy-focused recommenders give less reliable support to students with limited participation histories while popular resources dominate lists — and answer it with a Hybrid HKG-GRU framework that embeds a heterogeneous Knowledge Graph of course materials and models learner sequences with a GRU, then trains for robustness across learner groups (GroupDRO) and reranks for exposure diversity (Maximal Marginal Relevance). On Moodle logs from 152 students, 59 resources, and roughly 150,000 interactions it reached HR@10 = 0.68 and MRR = 0.41, but substantial popularity bias persisted at catalog level — evidence that bias mitigation is partial.

Semantic recommenders replace co-occurrence with structure. Liu, Sun, and Song (2026) build a knowledge graph of teaching resources, language concepts, skills, learner groups, and pedagogical attributes, and decompose every resource along four instructional dimensions — teaching context, cognitive level, technological feature, and cultural adaptability. Recommendation expands k-hop over the graph from a learner's stated requirements, refines candidates with a feature-based collaborative filter, and ranks them by a fusion coefficient that rises with the learner's ability, progress, and interest indices, so less-advanced learners get more structured guidance from the graph while higher-ability learners lean on their behavioral pattern. On the English subset of the MARS dataset (4,800 users, 14,200 resources, 132,000 interactions, sparsity 0.9981) it reached NDCG 0.625 and HR 0.751, roughly a 7–8% gain over the best neural baseline, and beat graph-aware baselines including RippleNet and KGAT on coverage and cross-domain accuracy. Ablation shows the signals are complementary (CF-only NDCG 0.584, KG-only 0.604), and the authors note these are ranking metrics, not evidence of learning effectiveness.

A third route avoids per-learner interaction data almost entirely. Hoq and colleagues (2026) extract pattern-based knowledge components from each code sample and recommend related practice activities by the similarity of their knowledge-component sets. On an expert-organized corpus of introductory Python materials, the approach aligned with the instructors' own conceptual bundles and beat knowledge-component and embedding baselines on ranking metrics — evidence that instructional alignment can come from the material's semantics where learner histories are thin.

A fourth route treats recommendation as a sequential decision rather than a ranking. ExRec (Ozyurt, Almaci, Feuerriegel and Sachan, 2025) builds a semantically grounded knowledge tracer — an Large Language Models (LLMs) annotates each question with solution steps and knowledge concepts, contrastive learning aligns question, step and concept embeddings, and a calibration loss lets the tracer predict a concept-level knowledge state directly — and then uses that tracer as the Reinforcement Learning environment in which a policy selects the next exercise. Two design choices matter for the recommender problem specifically: the student state is a compact recurrent encoding rather than the full exercise history, so long sequences stay

tractable in the replay buffer, and the reward is the change in predicted concept knowledge, computed without running inference over every question in the target concept. A model-based value estimation initialises the critic from the tracer, which improved continuous value-based agents across four tasks on XES3G5M (2,048 test students) and pushed them past discrete-action methods on the hardest one — recommending for the student's *weakest* concept, where the target changes at each step. Numbers are percentage-of-maximum knowledge improvement from a simulated environment, which is a weaker claim than measured learning, and the authors' own appendix notes that most tracing datasets record only a binary correctness label, so the misconception-level recommendation they sketch is not yet testable on existing data.

Prerequisites and Path Sequencing

Ranking a next item is easier than ordering a curriculum, because learning dependencies are directional. Cheng and colleagues (2026) argue that treating prerequisite discovery as ordinary link prediction fails on three properties of the relation: it is irreversible, its evidence is often multi-hop ($ci \rightarrow ck \rightarrow cj$) rather than a one-step learner transition, and its relevance is pair-specific, so a concept's representation should change depending on what it is paired with. Their ProPRL model adds an Irreversibility Constraint — an anti-symmetry regularizer penalizing high confidence in both directions of a pair — alongside a pair-conditioned gate weighting resource-aware evidence from a concept-resource hypergraph against behavior-aware evidence from a learning-behavior graph. It ranked first on all nine dataset–metric combinations across MOOC, LectureBank, and University Course datasets, improving on the strongest baseline by 1.96% to 6.11%, and the constraint raised the share of correctly ordered relations from 88.0% to 90.0%.

Once dependencies are modeled, a path becomes an optimization problem. Feng and Huang (2026) combine Bayesian cognitive diagnosis, knowledge space theory, and cognitive load theory: a Bayesian DINA model converged on EdNet data with 91.3% sparsity, and a shortest remediation path algorithm produced personalized paths averaging 3.82 steps — 22.4% more efficient than random paths and 23.6% more efficient than fixed full-coverage paths. In a randomized probability-learning experiment with 120 students, personalized-path learners finished in 57.6 minutes against 73.8 minutes for controls and outperformed controls on the post-test after controlling for pre-test. The study also tests *why*: personalized paths reduced cognitive load on all six adapted NASA-TLX dimensions, and cognitive load was the primary mediator of the effect on post-test performance (indirect effect 0.28 in the multiple-mediation model). A Hidden Markov Model identified Analytical Thinking as the bottleneck attribute, with the lowest forward transition probability (0.31) and the highest guessing parameter ($g = 0.28$).

PersonaPath pushes the sequencing question further by disputing the *unit* of the decision. Liu et al. (2026) contrast Exercise-Centric recommendation — infer the next item from interaction logs — with Knowledge-Centric planning, in which a planner reads an explicit learner persona, a mastery state and a stated target unit and selects the next textbook, unit and concept from a curriculum hierarchy (347 textbooks, 1,751 units, 4,092 concepts across 77 subjects, with 411 prerequisite edges verified to 99.5% precision at Cohen's $\kappa = 0.93$). The distinguishing case is the one logs cannot see: two learners with identical correctness records but different targets need different routes, and only the goal makes that visible. Their closed-loop evaluation of ten LLMs (1B–30B+) separates the dimensions an aggregate metric conflates — DeepSeek-V3.1 reaches 90.9% on prerequisite/hallucination validity but only 44.3% on adaptivity, for a 29.5% final pass rate in Basic Education and 14.6% in Higher Education, and no model exceeds 44.7% on adaptivity anywhere. Two ablations sharpen the diagnosis: removing the mastery field from the persona costs up to 26.1 points of

adaptivity while barely moving validity, and one-shot path generation raises validity by as much as 30.8 points while cutting adaptivity by 28.8 — curriculum-conformant sequencing is a far easier target than learner-conditioned sequencing, which is a caution against reporting path quality without a learner-alignment constraint (PersonaPath: Towards Knowledge-Centric Personalized Learning Path Planning).

Prerequisite structure also works as a diagnostic lens on the curriculum rather than the learner. Medhat and colleagues (2026) classify student questions to an AI teaching assistant against a GPT-4-extracted prerequisite graph, reaching 80.0% accuracy across 43 labels on 1,340 question events from 164 graduate students, and found topic-level question volume correlated with students' self-reported difficulty (Spearman's $\rho = 0.491$, $p = 0.008$). The interaction log becomes a map of where the curriculum's ordering is failing learners, at no added assessment burden.

Explaining and Auditing Recommendations

Ranking quality does not settle whether anyone should follow the ranking. Feldman-Maggor, Cukurova, Kent, and Alexandron (2025) adapt Hoff and Bashir's trust-in-automation model to AI recommendations and test it with 41 in-service chemistry teachers using the recommendation tool GrouPer. Explainability raised Trust indirectly, by raising understandability, and the *form* of the explanation mattered more than its presence: moving teachers from feature-importance ("data-driven") explanations to semantic, curricular-language ("domain-driven") explanations significantly increased understandability ($W = 80.5$, $p = 0.005$), learned trust ($W = 52$, $p = 0.002$), and acceptance ($W = 22.5$, $p = 0.003$), and all seven think-aloud teachers reported the domain-driven explanations as more influential. Two further acceptance drivers appeared, both situational rather than epistemic: pedagogical alignment (reported by 8 of 11) and workload reduction (6 of 11). Several teachers also said explanation alone was insufficient — they wanted classroom experience with the tool before relying on it, a strong claim that trust in a recommender is built over use, not delivered in a legend.

Fairness auditing asks a different question: whose recommendations are worse? The Graph-GRU study is a useful worked example because it names what its audit could not see. Fairness was operationalized through participation-based cohorts because the public Moodle dataset lacked achievement, prior knowledge, learning profiles, and demographic attributes, so the result is an audit of behavior across engagement levels rather than a full assessment of educational equity; a low-activity learner may be struggling, disengaged, or already familiar with the material. Explainability there takes the form of path-based and counterfactual analysis, with median counterfactual stability CR@10 = 1.0 for many learners but persistent catalog-level popularity bias reflected in high Gini exposure metrics. The lesson is that Bias Mitigation must be measured at the level of exposure and learner groups, not inferred from accuracy or from the presence of an explanation module, and that Human-in-the-Loop oversight is meaningful only if the human sees the group-level evidence.

Learning Paths in Practice

Paths are not only computed; they are designed. Divjak, Svetec, and Horvat (2026) turned Learning Analytics on the design process itself, analyzing the sequence of 29,064 teaching and learning activities across 554 courses planned in a free Balanced Design Planning tool. Markov chains and pattern mining surfaced a design grammar: Acquisition-type activities were the most common learning type (above 20%)

and the most common entry point, followed by Practice, Discussion, and Assessment (each 15–20%), and the strongest transition was Assessment → Discussion (0.332), ahead of Practice → Practice (0.317). The rule Acquisition → Assessment → Practice → Practice held at confidence 0.74 (lift 1.45), and learning type tracked the intended outcome's cognitive level: Acquisition fell from about 50% of activities at Bloom level 1 to about 20% at level 6. The authors warn that resemblance to flipped, inquiry-based, or project-based designs is not evidence of intent — but a recommender trained on such design data learns these habits, including a bias toward transmission-oriented opening activities.

At the other end of formal schooling, path structure becomes a AI Governance question. Szekely, Gal-Ezer, and Harel (2026) argue that AI-mediated access to knowledge warrants rethinking fixed higher-education curricula and propose "learnity graphs" — structured representations of learning as interconnected units of knowledge, skills, experience, and artifacts — spanning academic, professional, and personal learning. The proposal keeps the university's role in foundational knowledge while shifting emphasis toward Creativity and interdisciplinary integration, and it makes the learner a maintainer of their own graph, which is where it meets Self-Directed Learning and Self-Regulated Learning. Whether self-directed navigation leads somewhere constructive is not guaranteed: Shen and Arunrugstichai (2026) model two pathways from high-school learning climate to university GenAI use in a cross-contextual survey (N = 508), distinguishing constructive autonomous use from compulsive dependence.

One boundary worth stating: what recommenders currently do is closer to consultation than to collaboration. Mutlu Cukurova (2026) reconstructs what has historically been required before an interaction qualifies as collaborative — a negotiated, partly symmetric relationship, shared and negotiable goals, a low and shifting division of labor, and mutual modeling and socially shared AI Regulation in Education — and concludes that most current human-AI interaction is better described as consultation, governance, delegation, or instruction. His five-level taxonomy (transactional, situational, operational, praxical, synergistic) is a useful calibration: suggesting the next resource is an operational arrangement, and calling it a collaborative learning partner inflates the claim.

How This Page Relates to Personalized, Adaptive, and Tutoring Research

The three adjacent concept pages cover adjacent ground and should be read together with this one. Personalized Learning covers the *goal* — tailoring the whole experience, including goals, preferences, and pace, of which pathway selection is one component. Adaptive Learning covers the *mechanism* — the measure-model-adapt loop that changes content, pacing, and difficulty in real time. Intelligent Tutoring covers the *platform*, the canonical system that combines diagnosis with instructional interaction. This page covers the decision layer those pages presuppose: the ranking and sequencing technology itself. It is the home for collaborative-filtering and knowledge-graph recommender architectures, prerequisite-relation discovery and curriculum ordering, the explainability and fairness of ranked outputs, and the recommender-specific failure modes — cold start, popularity bias, over-narrowing, opaque ranking, and unequal recommendation quality across learner groups. A study reporting NDCG or coverage on interaction logs belongs here; one reporting learning gains from a tutoring dialogue belongs on the tutoring or adaptive-learning page.

Risks and Open Questions

The evidence base has a consistent shape: strong offline ranking metrics, weak evidence about learning. Both recommender studies above are evaluated on historical interaction logs and say so, and the CF–KG authors call explicitly for teacher assessments, learner studies, and outcome-based experiments. Popularity bias survived a fairness-aware training objective in one system, so the field cannot yet point to a reranking or regularization fix that reliably changes exposure, and fairness audits remain bounded by what LMS logs contain. Cold start is addressed architecturally, through semantic structure, but not tested on genuinely new users in live deployment. Path efficiency is better evidenced, yet the efficiency numbers still rest on one study and one algorithm family, and a shorter path is not automatically better if it removes the productive struggle a learner needs. The formal path-optimization work sharpens the point in both directions: guaranteeing a hard problem says little about a particular corpus, since a hill climber hit the top of the interleaving rubric on every real profile despite NP-completeness proofs, and a path graded 3.54 on a theory-derived rubric is still a path nobody has tested on learners, so rubric quality is a designer-facing proxy for outcome evidence rather than a substitute for it. The vocabulary is also unstable: Ikram and colleagues (2026), in a PRISMA review of 31 Scopus-indexed articles (2013–2025), report medium-to-large cognitive effects (g = 0.50–0.70) for AI-enabled adaptive systems that are heavily moderated by implementation quality and study design.

The same literature has begun to propose remedies for narrowing, though not yet to test them. Najem, Zaoui Seghroucheni and Ziti (2026) cluster 14,003 student records on 12 self-reported behavioral, psychological and environmental inputs into six profiles with K-Means++ and strong separation (Silhouette 0.62; η^2 = 0.770 on final grade, with a 40.17-point mean exam-score gap between the highest and lowest profiles), then map profiles to learning objects through an affinity score combined with a Felder-Silverman mapping matrix and a diversity regularization term ($\lambda = 0.30$) whose explicit purpose is to stop a recommender from collapsing into what a profile already prefers. The design is the contribution and the evidence is not: the recommendation layer is conceptual with no deployment or outcome measure reported, and the authors state that the clustering inputs are self-reported proxies rather than LMS interaction traces. It is a candidate answer to the regularization gap this page notes, still awaiting the validation the page says the field lacks.

Common Misconceptions

“A recommendation with a higher accuracy metric is a better learning path.” Ranking accuracy and instructional validity are different claims. On the English subset of the MARS dataset (**4,800 users, 14,200 resources, 132,000 interactions, sparsity 0.9981**) one system reached NDCG 0.625 and HR 0.751, roughly a **7-8%** gain over the best neural baseline — an improvement in predicting what a learner would engage with, which is not the same as what would teach them.

“Prerequisites can be treated as a symmetric similarity relation.” They cannot: prerequisite relations are **directionally asymmetric**, and a model that captures “these topics are related” has captured neither the direction nor the ordering. This is why prerequisite sequencing is a distinct problem from recommendation.

“Sparse data is a technical nuisance.” At the sparsity levels in this literature (0.9981) the system sees almost nothing, which makes cold start and popularity bias structural rather than fixable by tuning. A

recommender trained on that signal will systematically surface what is already popular, and quiet or unusual learners are the ones it cannot see.

“Explainability is a reporting feature.” Whether a teacher or learner can audit a recommendation is a legitimacy condition: a path a student cannot examine is one they cannot contest, which is a governance problem before it is an interface one.

Pedagogical Agent

> **Synthesis**: Pedagogical agents are AI-driven conversational interfaces embedded in learning environments that use pedagogical strategies (eliciting, telling, scaffolding) to support learner engagement, reflection, and metacognition. Designs vary from simple information providers to interactive dialogue partners that adapt to learner states.

Questions to Consider

- Think of a time a chatbot or tutor gave you a perfect answer that left you no wiser. What makes an AI 'teach' rather than merely 'solve'—and why might a benchmark score fail to capture that difference?
- The page finds that tutoring 'solving' scores and 'pedagogy' scores correlate only weakly across models. What should that tell you about evaluating an AI tutor on its ability to answer questions?
- Some designs give AI distinct roles—Teacher, Classmate, Mentor—and even keep a parent centrally involved (as in ParaTutor). In your experience, does giving an agent a clear role change how Learners interact with it?
- Real students often 'bypass' a chatbot's pedagogical framing when the agent's goals clash with the learner's own. Why might a learner rationally ignore good scaffolding, and what does that imply for assuming 'if we build it, they'll engage'?
- Would you rather learn from an AI that tells you things, one that asks you questions, or one that mediates a group discussion? How does your preference shape what you think a 'pedagogical agent' should be?
- From a simple info-provider to a fleet of specialized agents orchestrating a whole course—where do you think the value (and the risk) of conversational AI tutoring actually lies?

Introduction

A pedagogical agent is an interactive AI component within a learning system that engages learners through dialogue, questions, or prompts to support cognitive and metacognitive processes. Unlike passive dashboards or static feedback, pedagogical agents employ evidence-based tutoring strategies — such as eliciting learner self-assessments before providing Feedback, or Scaffolding Problem Solving through Socratic dialogue. The umbrella now covers everything from a single conversational intelligent tutor to fleets of role-specialized agents that lecture, mentor, facilitate collaboration, and even orchestrate course generation, all grounded in decades of intelligent-tutoring-systems research. - **An agent whose role is regulation rather than explanation.** Chen et al. (2026) built SSRLAgent to diagnose a group's shared regulatory state and prompt accordingly, and held a content-support agent constant across both conditions (Chen et al., 2026). Because both arms had an agent and a structured platform, the gains attach to adaptivity in the regulation prompts rather than to the presence of a conversational agent.

How pedagogical agents are studied in the knowledge base

- **Peer versus tutor is a role the interaction produces, and it is judged on social behavior.** Lin et al. (2026) had seven expert researchers solve quadratic equations with an adaptive agent carrying a Big Five persona and motivational modulation, then interviewed them. Participants read the agent as a peer when it created a non-judgmental space, reasoned tentatively, showed appropriate imperfection and respected their pace, and as a tutor when it agreed blindly, disclosed the answer early or fixed the direction of travel — a shift driven by control rather than by correctness. One participant found the agent's mistakes endearing while another found them useless, so peer-likeness and peer-usefulness diverge, and fabricated shared history ("claims I've said some things which I didn't") broke trust faster than any wrong answer. **Design and architecture of conversational agents.** A recurring thread is how agents are structured, not just what models power them. The conversational AI tutors framework argues that proven ITS technologies — Knowledge Tracing, affect detection, student modeling — should anchor generative tutors, keeping the diagnostic backbone while Generative AI supplies flexible dialogue. Multi-agent designs push this further: MAIC replaces the MOOC's "one video for N students" with a Large Language Models (LLMs)-driven classroom of Teacher, Assistant, Classmate, and Analyzer agents to deliver personalized learning at scale, while LecturaAgents adds an embodied ProfessorAgent whose TASA algorithm aligns visible teaching actions (handwriting, highlighting) with learner profiles. Even parent–child tutoring becomes a two-agent problem in ParaTutor, where role-separated scaffolding keeps the parent centrally involved instead of letting a generic chatbot displace them. The same role-based logic appears in Instructional Agents, where Teaching Faculty, Designer, TA, and Program Chair agents collaborate across ADDIE to generate course materials.

A complementary use of role-based agents targets teacher practice rather than student learning: Mohne et al. (2026) combine pedagogical student personas, memory grounded in actual course material, and an LLM-as-a-judge speaker oracle so novice instructors rehearse a small-group section — 254 optional sessions averaging about 16 minutes each, at roughly $0.05–$0.10 per session.

Teaching versus solving behavior. A central empirical finding is that answer-production is not learning support. Measuring whether LLM tutors teach or solve shows solving and pedagogy scores on tutoring benchmarks correlate only weakly (r = 0.421 across eight models), arguing that benchmarks must report pedagogy-oriented criteria — guiding questions, calibrated hints, non-disclosive scaffolding — separately. This aligns with tutoring-specific vs general AI evidence: pedagogically designed tutors with Guardrails mitigate the exam-score drops and suppressed reasoning that raw general-purpose chatbots produce, preserving desirable difficulties and productive struggle rather than short-circuiting them. Yet benchmarks can overestimate how well even scaffolded tutors work in the wild. Rethinking scaffolding in LLM tutors finds that real students frequently bypass a chatbot's pedagogical framing, a rational response to a mismatch between the agent's goals and the learner's own — so uptake must be evaluated, not assumed.

Role in tutoring and collaboration. Agents are increasingly positioned not as answer-givers but as facilitators and mediators. Niari's pedagogical mediator framework reconsiders AI in collaborative learning as an interactional, epistemic, and regulatory mediator — scaffolding participation and shared AI Regulation in Education without displacing teacher or learner agency. Concretely, collaborative AI tutoring (ProPACT)

treats collaboration itself as the object of instruction, forecasting dyadic breakdowns up to 30 seconds ahead and delivering minimally intrusive scaffolds that preserve Metacognition. Embodied inquiry with AI as facilitator shows an AI can complement hands-on model-building by facilitating application of a constructed model, while robot-assisted language learning meta-analysis finds outcomes track how a robotic agent is positioned in instruction (group-based interaction) more than its technical sophistication. Whether the *role* an agent plays is enough, or whether it must also *adapt its behavior*, is questioned by Liao (2026): an elementary "book talk" study found a fixed "student peer" companion sustained longer interactions yet suppressed student agency and hit an "affective ceiling" (weak emotional/future-oriented reflection), arguing that role *labeling* must be paired with role-*adaptive* interaction logic rather than a monolithic single-role design.

Ethics Training Agents (Seo et al., 2026) shows what happens when a pedagogical agent is asked to moderate rather than teach: an LLM facilitator handling turn-taking (stacking with 15-second hand-raise windows), time management (auto-advancing a stage to wrap-up after 9 minutes), and incremental batch summarization reduced participants' cognitive burden and gave them a sense that the discussion was "on track" — one participant contrasted it favorably with ChatGPT, which "can often feel disorganized or make it hard to see the progress of ideas." The same study exposes the ceiling of persona-based agents: the three distinct ethical-orientation agents were rated significantly below human peers on contribution, diversity and influence (Kruskal-Wallis $p < .001$), and participants asked for process-oriented ("how the agent reasons") rather than conclusion-oriented output.

Where conversational agents are (and aren't) used — the umbrella-review picture. The umbrella review of conversational AI agents (Ganguly et al. 2025, 34 reviews) quantifies CAI utilization: teaching and learning support (97.1% of reviews), psychological and motivational support (91.2%), and metacognitive and personal development (88.2%) lead, while administrative support (50%), research and information management (52.9%), and healthcare/medical support (41.2%) trail. It also flags that CAI research lacks end-to-end design guidance, CAI-specific usability methods, and concrete classroom-orchestration strategies for the teacher's role — reinforcing that pedagogical-agent design must be HCI-grounded, evidence-based, and attentive to AI Literacy.(Conversational AI agents in education: an umbrella review of current utilization, challenges, and future directions for ethical and responsible use)

Role orientation is a design variable, not a stylistic choice. The physics agent comparison (Wang et al. 2026, 59 learners) isolates prompt-specified role while holding model, platform, and temperature fixed: a teacher-centered agent grounded in a bounded textbook source and answering from the instructor's perspective, versus a student-centered agent configured with knowledge of students' understanding and scripted to diagnose misconceptions, name the concept, and transfer to an analogous case. The student-centered role won on every measured outcome — post-test performance, lower extraneous and higher germane cognitive load, flow experience, and perceived empathy — even though the teacher-centered agent was the one optimized for accuracy and textbook fidelity. This makes *role and interaction pattern* a first-class design parameter alongside prompt and model choice, and shows that empathy can be engineered from conversational structure rather than a differently trained model (Affective Computing).

Authoring intent does not guarantee enacted pedagogy. When 27 middle school teachers configured a teacher-facing chatbot authoring tool, an evaluation of 108 bot-level criterion ratings found generated responses aligned far better with responsiveness (88.9%) and persona (81.5%) than with rules (70.4%) or the stated purpose (59.3%), which the authors frame through pedagogical forms of Norman's Gulf of Execution

and Gulf of Evaluation — configurable controls alone did not make the teacher's instructional intent visible in the bot's behavior (Riahi et al. (2026)).

Agents in immersive and extended-reality settings. Ross and Kaspar (2026) extend the concept into extended reality (AR, augmented virtuality and VR) with ACLIME, a conceptual framework that — unlike CAMIL, CATLM-VR and TICOL — keeps the agent inside the model. It names two interaction modes drawn from the literature: the tutor, offering guidance, encouragement, reflective questioning and explanations, and the role-playing partner, which occupies a defined role inside a scenario such as a local on a climate-change field trip or a negotiating counterpart in corporate training. The agent's body (head-only through full body) and behavior are treated as design surfaces: visual versus behavioral realism, flexible AI control versus fixed rule-based scripting, synthesized versus pre-recorded speech, and nonverbal channels including gaze, gesture and proxemics. Immersion and body-based interactivity are argued to multiply the social cues behind social presence — behavioral realism, not visual realism, is proposed as the decisive predictor — while the learner's own virtual body adds an embodiment dimension (body ownership, virtual own body agency, self-location) and the proteus effect. The framework's explicit trade-off is cognitive: immersion and the agent's mere presence can raise cognitive load even as social interaction with the agent lowers it through the collective working-memory effect, and a temporal layer (familiarization, maturing human-agent relations, novelty decline, developing cybersickness) is added to the usual design variables. Its status is deliberately provisional: hardly any empirical work yet tests pedagogical agents in immersive media, and long-term learning outcomes as well as learner characteristics sit outside the model.

The agent's surface is a separate design axis from its pedagogy. AI Avatars and Synthetic Instructors treats the avatar's identity cues, presence and trust effects in its face and voice as outcomes worth measuring on their own, whatever the agent's scaffolding does.

Evaluation and benchmarks. Measuring a pedagogical agent requires testing pedagogy, not content. The Teaching Monster Challenge benchmarks Pedagogical Content Knowledge by asking agents to adapt a lesson to a specified learner persona, finding systems strong on content but weak at adapting it — and revealing that LLM-judges mis-rank strong systems. EduAgentBench evaluates agents across professional pedagogical judgment, situated multi-turn tutoring, and canvas-style workflow completion, showing models fall short of professional teaching standards. AI-generated interactive fiction adds a design-evaluation angle: coherence and quiz integration, not generation capability, limit usefulness for the student experience. **Stress-test persona robustness over multiple turns.** Shouqi et al. (2026) ran six escalating attacks against role-playing agents with an automated Judge: multi-strategy testing cut robustness by 0.17–0.20 versus a single-strategy baseline, and critical failures clustered after turn 5–6, so short or single-turn evaluations overestimate persona stability and ethical adherence.

- **A peer agent whose fallible suggestions are the point.** Copa pairs log-contextualized retrieval with GPT-4o and a fifteen-chunk task-specific knowledge base, and summarizes each student segment agentically: it compares the student's model to an expert version, diagnoses the expressed problem, and names what to retrieve. Across a classroom study with 16 students and two focus groups, all participants said its guidance supported their problem solving and was accurate, and all would use it again. Several also asked for straight answers, and some assumed a suggestion was correct until their model got worse. The authors read that as the cost of designing an agent to prompt evaluation rather than to answer (Cohn et al., 2025).

Practical guidance

Design for the learner's agency, not the model's convenience. Favor tutoring-specific guardrails — Scaffolding, hints, Socratic questioning, misconception targeting — over raw answer generation, since solving and teaching diverge. Distribute support by user role (parent vs child, peer vs peer) rather than through a single generic interface, and treat collaboration as a valid target for scaffolding. Don't assume students will take up scaffolding; evaluate uptake in real contexts. Build human oversight into authoring — as PromptDecipher does by making teacher QA of bot responses a first-class activity — and choose cheaper backends where quality holds. Report teaching and solving scores separately, and validate generated content with users rather than assuming generation equals usefulness.

Learner preference is a poor proxy for scaffolding quality: students in AI-supported mathematical modeling performed best with Peer and Teaching Assistant roles yet rated the more directive Tutor and Excellent Student roles highest on usefulness and Self-Efficacy (Zhu, Yang and Yang (2026)).

A review of 46 studies of AI agents in computer-supported collaborative learning distinguishes cognitive scaffolding, social facilitation and instructional orchestration, and finds cognitive gains consistent while behavioral, social and emotional outcomes are context-dependent — so the agent's function should be chosen for the outcome it is meant to produce (Ba et al. (2026)).

Connections to related concepts

Pedagogical agents sit at the intersection of Intelligent Tutoring (their diagnostic backbone of Knowledge Tracing and student modeling) and Generative AI/Large Language Models (LLMs) (their delivery engine). They operationalize Scaffolding and Feedback, aim at Metacognition and Self-Regulated Learning, and increasingly target Collaborative Learning. Safety concerns recur across Pedagogical Safety, authoring quality, and the risk that agents offload learning rather than support it. All of this is evaluated through AI Ed Evaluation and benchmarks that must measure teaching, not just solving.

Crucially, pedagogical agents are judged by their learning gains, not by how fluently they respond. The knowledge base's evidence is that agents produce durable gains when designed as tutoring-specific coaches with guardrails — tutoring-specific AI consistently outperforms general-purpose chatbots — and can harm learning when they substitute for the learner's effort (the guardrail RCT, LLM-reliance and grades). Measuring an agent's Learning Gains therefore requires unassisted, transferable outcome measures, not in-tool performance.

Better feedback is not the same as better learning: customizing an agent with knowledge bases and a workflow raised feedback accuracy and specificity but left self-regulatory behaviors, learning experiences and outcomes unchanged, and its gain advantage appeared only under directive feedback (Han et al. (2026)).

Common Misconceptions

- **"Authoring intent determines what a pedagogical agent does." Authoring intent does not guarantee enacted pedagogy.** When **27 middle school teachers** configured a teacher-facing chatbot authoring tool, evaluation of 108 bot-level criteria showed the enacted behavior diverged from what teachers intended. The tool mediated the pedagogy.

- **“A pedagogical agent moderating discussion is a solved role.”** Ethics Training Agents (Seo et al., 2026) shows what happens when an agent is asked to **moderate rather than** instruct — a qualitatively different demand from answering questions, and one the literature treats as unsettled.
- **“The evidence base for computer-assisted instruction is thin.”** A synthesis (**2025, 34 reviews**) quantifies CAI utilization across teaching and learning support (**97.1% of reviews**), psychological and motivational support (**91.2%**) and **metacognitive** support. Breadth of reviewed application is extensive, which makes the gap one of enacted quality rather than coverage.

Affective Tutoring

> Integrating emotional awareness into AI tutoring systems can yield measurable pedagogical gains, but the same affective sophistication risks amplifying harms if learner agency is eroded by empathetic-seeming automation.(MathBuddy: Affective Math Tutoring)(Critical AI Tutors: Empower or Enslave?)

Questions to Consider

- An affective tutor that senses and responds to your emotions can improve outcomes — one study gained a +23 point win rate over a non-affective tutor. But what might that emotional responsiveness cost the learner's own agency?
- Empathy in a tutor can feel supportive, yet it can also create parasocial dependence or mask metacognitive disengagement. How can you tell whether feeling understood by a machine is helping you learn or making you reliant on it?
- Too-supportive tutoring can suppress the frustration that drives productive struggle. When does emotional comfort help learning, and when does it short-circuit it?
- Facial monitoring signals attentiveness but raises real privacy concerns. What would you want to know before a tutor tracked your facial expressions while you learned?
- Design principles suggest affective data should inform, not replace, learner autonomy — you should control what you disclose and know when your emotions are being inferred. How would you feel if a tutor quietly changed its strategy based on your detected mood?
- Students may attribute an AI tutor's emotional support to genuine relationship, reinforcing reliance on it. What's the difference between a tutor that genuinely cares and one that is designed to appear like it cares?

Introduction

MathBuddy dynamically models student affect using two modalities:

- **Conversational text** — semantic cues for frustration, confusion, confidence
- **Facial expressions** — real-time video capture of emotional state

Emotions are aggregated from both modalities and mapped to relevant pedagogical strategies before prompting the Large Language Models (LLMs) tutor, yielding emotionally-aware responses.

Results: - **+23 point win rate** improvement over non-affective baseline - **+3 point DAMR score** gain at overall level - Evaluated across **eight pedagogical dimensions** plus user studies

The finding validates a long-standing hypothesis in educational psychology: positive/negative emotional states impact learning capability, and accounting for them improves tutoring outcomes.

The Risk: Empathy as a Trap

Favero et al. (2025) warn that emotional engagement with AI tutors carries underappreciated risks:

Affective tutoring benefit	Corresponding risk
Emotionally-aware responses feel supportive	Students may form **parasocial dependencies** on the tutor
Empathy reduces anxiety	Reduced anxiety may mask **metacognitive disengagement**
Affective calibration personalizes pacing	Deep personalization can **reduce transfer** to non-adaptive contexts
Facial monitoring signals attentiveness	Continuous video capture raises **privacy concerns**

The authors argue that emotional risks are part of a broader pattern of **erosion of Self-Efficacy, Learner Agency, and Well-Being** when AI use is unchecked.

The risk also falls on people who never open the tutor. Shastry and Gray (2026) found that willingness to provide emotional support yourself declines as you believe a system can provide it, and that belief was causal in their second experiment: reading ordinary news coverage about empathic AI was enough to raise offloading, entirely through perceived capacity. Their fourth study adds a social cost the individual-level framing misses. Told that a student had gone to a chatbot for support, participants said they would offload less than if the student had gone to a friend. They then wrote fewer empathy words and more indifference words about that student, and rated them as stranger and more desperate. Social-emotional provision can therefore thin out around the tutor even when nobody using it reports a change.

Design Principles

1. **Affective data should inform, not replace, learner autonomy** — The tutor adapts its strategy; the student retains control over disclosure
2. **Transparency about affect detection** — Students should know when and how their emotions are being inferred
3. **Affect-as-one-signal-among-many** — Combine with cognitive state (e.g., Interpretable Knowledge Tracing) and behavioral engagement
4. **Privacy-by-default for Multimodal AI sensors** — Facial/video data requires stronger protections than text-only inference
5. **Trigger on trajectories, not point estimates** — Ordered affect shows short-range persistence and directional transitions, and probe-caught reports (self-loops around curiosity and confusion) are a different measurement from self-caught ones (frustration, surprise, conflict), so interventions should key on the sequence rather than summary frequencies (Anindho et al. (2026)).

A boundary on affect inference from dialogue: Zhou, Li and Zhang (2026) update a five-dimension learner profile at each turn — including an emotional dimension — but extract signals with keyword dictionaries, so a student who expresses frustration without the predefined keywords is not profiled, and profile accuracy has not been validated against expert judgment.

Relationship to Broader Safety

Affective tutoring intersects with SafeTutors in the motivational-affective harm dimension. An affective tutor that is "too supportive" may suppress the frustration that drives productive struggle and self-regulation. See also The LLM Fallacy: Misattribution in AI-Assisted Cognitive Workflows — students may attribute emotional support to genuine relationship, reinforcing reliance.

Common Misconceptions

"The +23 point win rate shows affective tutors teach better." It shows something narrower. The comparison is a win rate against a non-affective baseline for one system, MathBuddy, scored across eight pedagogical dimensions and user studies; a win rate is a preference outcome, not a measure of durable learning in a real course. The honest claim is that affect-aware strategy selection beat affect-blind strategy selection on judged response quality, which is a strong result about interaction and a weak one about Learning Gains.

"If the tutor feels empathetic, the student is being helped." Feeling understood and being taught are separable, and the gap between them is where the harm sits. Favero et al. identify parasocial dependence as the characteristic failure: a student can form a relationship with a system designed to appear caring while their metacognitive engagement quietly drops, and the empathy itself makes the disengagement harder to notice. The misattribution literature is the other edge of the same knife, where students credit the system with genuine relationship.

"More emotional support is always safer than less." Beyond some point support becomes interference. A tutor that reliably removes frustration can suppress the productive struggle that self-regulation depends on, which is why SafeTutors treats motivational-affective harm as a distinct safety dimension rather than an absence of benefit.

"A tutor that detects emotion from a face knows the student's state." Affect is inferred, not observed, and the inference is weakest exactly where the stakes are highest. Zhou, Li and Zhang (2026) maintain an emotional dimension in a five-dimension learner profile but populate it with keyword dictionaries, so a student who expresses frustration in words the dictionary does not contain is simply not profiled, and the profile has not been validated against expert judgment. Facial capture adds a continuous video stream and a privacy exposure that text inference does not.

"Emotion measurements taken at different moments are interchangeable." Anindho et al. (2026) find ordered affect shows short-range persistence and directional transitions, and that probe-caught reports, the self-loops around curiosity and confusion, are a different measurement from self-caught ones such as frustration and surprise. Averaging the two into a summary frequency discards the sequence that carries the signal.

Putting Affective Tutoring into Practice

For instructors

- Treat empathy as a delivery mechanism, not as evidence of learning. Pair any affect-aware tool with a cognitive check you can see, such as work products or knowledge tracing output, and do not let a student's felt experience stand in for diagnostic evidence.
- Disclose inference explicitly. Students should know an emotional state is being estimated, from what inputs, and be able to decline the camera without losing access to tutoring.
- Watch for the student who reports the tool "gets" them and whose independent work is not improving. That combination is the parasocial signature, not a success story.

For developers

- Make affect one signal among several. Combining it with cognitive state and behavioral engagement prevents the system from re-optimizing a lesson around a misread expression.
- Trigger interventions on trajectories rather than point estimates, keying on the sequence of states, since persistence and directional transitions are the informative part.
- Default to privacy-protective sensor handling, and treat facial or video input as a strictly higher tier than text inference, requiring its own justification and consent.
- Do not ship a keyword-dictionary affect layer as if it were detection. If you cannot validate the classifier against expert judgment, expose it as a coarse flag rather than labeling a student "frustrated."

For researchers

- Report the baseline your win rate is measured against, and state plainly that it is a comparative judgment. Then measure what the field actually needs: transfer to non-adaptive contexts, retention after the tutor is withdrawn, and whether gains hold when the emotional channel is off.
- Validate affect profiles against expert judgment before using them as independent variables.

Affective Computing

> **Affective computing** in education uses physiological and behavioral signals to sense learner emotion and adapt instruction — see A formative study of brief affective text as a complement to wearable sensing for longitudinal student health monitoring, An Interpretable Closed-Loop Intelligent Tutoring System for Multimodal Affective Feedback in Asynchronous Presentation Training, and MathBuddy: Affective Math Tutoring. The knowledge base also documents emotional risks of AI interaction, including Sycophantic AI makes human interaction feel more effortful and less satisfying over time and "Stuck in a Spiral": Shame and Guilt as Social Regulators of AI Use in Computing Education.

Questions to Consider

- If a computer could sense that you're frustrated, confused, or bored and adapt its teaching to your mood, how might that improve your learning — and what might it get wrong about you?
- Emotion-aware tutoring can boost engagement, but empathetic-seeming automation carries risks: over-reliance, parasocial dependency, and privacy concerns from continuous monitoring. Where is the line between being understood and being surveilled?
- An AI that affirms and 'understands' you can feel good — but research shows such AI can displace real relationships and erode critical judgment. How does feeling supported differ from being genuinely supported in a learning setting?
- Facial expression and text can both signal emotion. Should a tutor adapt its teaching based on your emotional state — and what kinds of emotional inference would you want it to act on versus never act on?
- If AI relieves your frustration by reducing difficulty too readily, you might stop struggling productively — and struggle is often where deep learning happens. How should a tutor decide when to comfort and when to challenge?
- Continuous affective monitoring raises real privacy questions. Under what conditions would you be comfortable with an AI reading your emotions in order to adapt your learning?

Introduction

Sensing emotion to adapt instruction

Affective computing aims to make AI systems emotionally aware so they can respond to how learners feel, not just what they do. In education this means sensing frustration, confusion, confidence, boredom, or engagement and adapting instruction accordingly. MathBuddy demonstrates the approach by modeling affect from two modalities — conversational text and real-time facial expression — and mapping aggregated emotional state to pedagogical strategies before prompting the tutor.

The signals themselves are ambiguous: a single expressive channel cannot reliably distinguish distress, effort, embarrassment, fatigue, or strategic self-presentation without the person, task, culture and situation

that produced them — "contextual under interpretation" — so a classifier reading the visible signal alone risks recommendations that are plausible but pedagogically wrong (Zhang et al. (2026)).

- **Emotional and reflective LLM support in middle-school math:** Rief et al. (2026) layered mindfulness onto an algebra tutor for 7th graders via dynamic chats, breathing exercises, and mindful error-feedback language. In a small classroom RCT (42 completers of 252 participants) the mindful version reached similar algebra learning in less time and with fewer requested hints than cognitive support alone — higher learning efficiency and more balanced Help-Seeking — though state-math-anxiety reduction did not differ significantly between conditions.

The benefits and the risks

Emotion-aware tutoring can yield measurable gains, but the same sophistication carries risks:

- **Benefits.** Accounting for emotional state can improve engagement and outcomes; learners who feel understood persist longer, and recognizing frustration early enables timely Scaffolding or Adaptive Learning adjustments.
- **Risks.** Empathetic-seeming automation can foster Over-Reliance and parasocial dependency, mask genuine metacognitive disengagement, and raise Privacy concerns from continuous affective monitoring. AI sycophancy is a central affective risk: emotionally ingratiating AI that affirms rather than challenges can erode critical judgment and even displace real human relationships — Ibrahim et al. show that sycophantic AI led users to seek personal advice from the AI nearly as often as from close friends and family, with lower satisfaction in real-world interaction. Defining AI Fatigue in Academic Contexts: Dimensions, Indicators, and a Stage-Based Model Using Grounded Theory and New AI-Driven Tools for Enhancing Campus Well-being: A Prevention and Intervention Approach further connect affective AI to learner Well-Being.
- **Engagement is not a proxy for learning.** Engagement and learning came apart under brain sensing: a constrained, adaptive interface increased cognitive engagement ($p = .018$) while the unrestricted chatbot yielded larger learning gains ($p < .03$, $d > 0.80$), so an affect signal can misalign with from the outcome it serves (Clin Deffarges et al. (2026)).

Affective computing and broader AIED

Affective computing sits at the intersection of Affective Tutoring (its pedagogical application), Learner Modeling and Adaptive Instruction (representing the whole learner, including emotion), and Learning Analytics (deriving signals from learner data). It connects to Intelligent Tutoring design and to Pedagogical Safety — the principle that AI should support, not manipulate, learner emotion.

- **Real-time, edge-based classroom emotion monitoring.** Nguyen et al. (2026) build an emotion-aware classroom quality assessment system that pushes affective computing into authentic, large-scale settings. Tailored for **IoT/edge devices**, the system addresses load balancing and latency while coordinating multiple agents to capture students' emotional and engagement patterns in real time. It was evaluated on the **Classroom Emotion Dataset** (1,500 labeled images and 300 classroom videos from real Vietnamese K–12 classrooms) with a focus on multi-person, in-the-wild affective interaction — a demonstration of scaling emotion recognition from lab models to

deployable classroom monitoring, alongside the privacy and Pedagogical Safety considerations such monitoring raises.

- **Emotionally intelligent assessment agents.** AIvaluate, an Large Language Models (LLMs)-augmented emotionally intelligent conversational agent, reduced student anxiety and social pressure during performance-based assessments while preserving usability.
- **Empathy engineered through prompt design, not sensing.** Affective support does not require affect detection: Wang et al. (2026) obtained a large difference in *empathy perception* (21.27 vs. 18.24; r = 0.53) between two LLM physics agents that differed only in prompt-specified role and conversational moves — perspective-taking openings ("You have this question because…"), misconception diagnosis, and a comprehension check at the end of each round — while model, platform, and temperature were held constant. This is a useful counterweight to sensor-driven affective computing: the perceived emotional quality of a Pedagogical Agent can be designed into the interaction script, while also reminding designers that perceived empathy is a self-report construct rather than evidence of genuine affective understanding (Student-AI Interaction).
- **Alerts that cue a teacher rather than adapt a tutor.** Swidan (2026) deployed Dash4Emotion in a high school geometry classroom, where red-framed rectangles marked students read as experiencing negative emotion; across twenty identified episodes (five reported), what shifted engagement was the teacher's response to an alert, not the alert itself. The design point is that affect sensing can feed a human decision instead of an adaptive tutor's next move — with the study's own caution attached: it reports no validation of the facial-expression detection, so the signal is a prompt for teacher interpretation rather than evidence about a student's internal state.

Common Misconceptions

- **"More engagement means more learning."** A brain-sensing study found a **constrained, adaptive interface raised cognitive engagement (p = .018) while the unrestricted chatbot produced higher learning gains**. The interface that engaged more taught less. Engagement is not a proxy for learning, and optimizing it can move the outcome the wrong way.
- **"Emotional support is a soft add-on to cognitive support."** In a small classroom RCT (**42 completers of 252 participants**), the mindful version reached **similar algebra learning in less time and with fewer requested hints** than cognitive support alone. The affective component changed efficiency rather than ceiling, which is a different and more interesting claim than "it helps learning."
- **"Small-sample affective findings transfer."** 42 completers from 252 participants is a both encouraging and fragile design: the completion rate is itself a finding about who persisted, and the effect is bounded to that group.

Sensor and Gaze Analytics

> **Sensor and Gaze Analytics** — the use of eye tracking, electroencephalography, electrodermal activity, heart-rate variability, and camera-derived posture to infer learner states such as attention, engagement, cognitive load, and affect. In AI in education these signals promise a continuous, non-verbal view of learning that quizzes and self-reports cannot supply. They also sit at the center of the field's hardest inference problem: a sensor records a body, not a mind, and every claim about what a learner thinks or feels is an interpretation layered on that recording (Kim and Han, 2026).

Questions to Consider

- A webcam can show that your eyes stayed inside a video player for a whole lecture. Does that mean you were paying attention?
- If a tutor could estimate your cognitive load in real time, should it act on that estimate without asking you first?
- A student's gaze may leave the screen because of a tic, a visual impairment, or a cultural norm. What does a "low attention" flag mean for that student?
- Should a university be allowed to collect brain and heart data for course improvement, and what would real consent require?
- A "75% engagement accuracy" figure sounds precise. Which layer of engagement did the sensor actually reach, and which did it miss?
- Proctoring now reads posture and head movement. Where is the line between detecting misconduct and judging a body?

Introduction

Sensor and gaze analytics describe a family of methods that turn physical measurements of a learner into educational inferences. The measurements include where the eyes rest and for how long, the electrical activity of the scalp, sweat-gland responses, beat-to-beat variation in heart rate, and the position and motion of the head and torso. The inferences include attention, engagement, cognitive load, confusion, stress, and, in assessment settings, suspicion.

The appeal is straightforward. Self-reports are retrospective and coarse, and quizzes sample learning at a few moments. Sensors run continuously and cost the learner little conscious effort. That combination has made sensing central to Learning Analytics and Learner Modeling and Adaptive Instruction, and it has produced a large literature in which the sensing is technically impressive and the interpretation is thin.

A systematic review of 23 studies pairing AI with Embodied Learning makes the imbalance concrete. Analysis and evaluation accounted for 40.0% of coded AI roles, and recognition and detection for 22.5%, while feedback and coaching took 15.0%. Sensing roles made up 62.5% of role tags against 35.0% for participatory ones (Kim and Han, 2026). The field is better at watching learners than at changing what happens next.

What each signal actually measures

Gaze and fixation. Eye trackers report where the eye points, how long it dwells, when it saccades, and how widely it disperses. Screen-based systems such as WebGazer estimate gaze from a webcam, while glasses track the eye directly. TutorLoop converts gaze into two quantities: attention as the percentage of gaze points inside the content area, and workload as gaze entropy, on the reasoning that dispersed gaze tracks cognitive load (TutorLoop, 2026). Ollie, a gaze-informed assistant for children, instead defines areas of interest in a picture and triggers narration when a child looks at one (Wu et al., 2026).

Electroencephalography. EEG records voltage fluctuations across the scalp at high temporal resolution. It is the only signal in this family that reaches cortical activity directly, which is why it attracts assessment research. Practical education systems use dry electrodes and few channels: E3Sense took four dry EEG channels at 125 Hz and analyzed two frontal ones (Anupkrishnan et al., 2026). Research-grade rigs take the opposite approach: Kosmyna et al. (2025) used 32-channel EEG to compare students writing with an LLM, a search engine, or no tool, and found the weakest neural connectivity in the LLM group (Kosmyna et al., 2025). That study is also the clearest warning about single-channel evidence, since its central claim rests on an optional crossover session that only 18 of 54 participants attended.

Electrodermal activity. EDA measures sweat-gland conductance, an index of sympathetic arousal. It responds to stress, effort, and emotional intensity, and it cannot distinguish among them. The same construct appears in wristbands and in forehead electrodes fixed a few centimeters apart by an eye-tracker frame (Anupkrishnan et al., 2026).

Heart rate and heart-rate variability. Heart rate tracks arousal, and variability between beats indexes autonomic recovery. In a year-long study of 458 students wearing Oura rings, emotional-exhaustion language tracked lower sleep efficiency and lower heart-rate variability (Affective Text and Wearable Sensing, 2026). Neither measure identifies a cause.

Camera-based posture and motion. A proctoring system can extract seventeen body landmarks per frame and derive posture deviation, head-movement trend, and upper-body motion (Arif et al., 2026). This measures movement. Calling it suspicious behavior is a separate, unsupported step.

These signals differ in sampling rate, noise, and instrumentation burden. E3Sense aligned twelve EEG, six eye, and three EDA windows into a shared 120-second representation with 166 dimensions (Anupkrishnan et al., 2026). EduGage ran seven device types at once and concluded that lightweight combinations carried most of the usable signal (Leng et al., 2026).

What the signals are used for

Engagement detection in video learning. E3Sense asked 30 university students to rate five segments per video, producing 450 ratings. A fused model reached 75.0% balanced within-one-level accuracy against a 63.0% mode baseline on held-out participants (Anupkrishnan et al., 2026). EduGage reported an MAE of 0.81 and 83.75% within-one accuracy across 16 participants and 715 probe windows (Leng et al., 2026). Both treat the estimate as approximate.

Attention estimation in classrooms. A multimodal transformer fused facial images with wearable signals on DIPSER, a naturalistic dataset of 57 subjects, and reached an MAE of 0.283. Its edge over a visual-only

baseline was modest, and the authors conclude that facial features were the primary information source (Fragkiadakis et al., 2026).

Cognitive load and feedback timing. TutorLoop used gaze-derived attention and workload to choose among four feedback types with a reinforcement-learning agent. Across 187 participants the full system intervened less often than baselines yet improved attention and lowered workload (TutorLoop, 2026).

Proctoring and integrity. Pose-based proctoring reports near-ceiling performance on its own labeled scenario set: 99.56% accuracy and an AUC of 0.9957 (Arif et al., 2026). Wearable AI changes the same problem from the other side. Smart glasses remove the gaze drop and posture shift that invigilation relies on, a condition Corbin and colleagues call dual transparency (Corbin et al., 2026).

Affect and wellbeing. Physiological signals collected during exams predicted grade categories, with random forest reaching a mean of 0.96 across 30 replicates (Yamazaki and Rimal, 2026). The top predictors were electrodermal activity, accelerometer movement, and skin temperature. That is arousal and motion, not comprehension.

Assessment research. EEG has been tested as a direct measure of familiarity and of mental representation. Both lines are promising and both remain exploratory, which the next section takes up.

The inferential gap

Every use above depends on a chain: a physiological or behavioral event, a feature computed from it, a model trained on labels, and a claim about a mental state. Each link leaks.

The label is often the weakest link. E3Sense predicted learners' own segment ratings, and 63% of those ratings sat at the two engaged levels. A model can score well by learning the distribution rather than the state. When the researchers added learners' own definitions of engagement, accuracy rose from 64.6% to 71.5%, which suggests the labels and the signals were measuring partly different things (Anupkrishnan et al., 2026).

Validation can inflate the model. A benchmark of fifteen models for EEG-based familiarity prediction reached 0.9853 F1 under stratified cross-validation. Trial-independent Group K-Fold, which respects temporal structure, dropped the peak to 0.6038 F1 against a 25% chance level (Nanayakkara and Halloluwa, 2026). The first number describes leakage; the second describes learning.

A neural correlate is not a score. Reconstructed images from EEG correlated with test performance at R^2 = 0.79 across 55 participant-video observations. Correctly answered items also showed higher semantic similarity than incorrect ones. Yet one participant produced high-quality reconstructions and answered incorrectly, so reconstruction quality cannot be read as correctness (Su et al., 2026).

Attention is not learning. In TutorLoop, attention correlated with learning at r = 0.017, while workload correlated negatively at r = -0.168 (TutorLoop, 2026). A system that maximized the attention signal would have optimized something close to noise.

A physiological profile is not a diagnosis. Exam stress models predict a grade category from arousal and movement, and the authors insist the output belongs beside personal circumstances and mental-health context rather than in a high-stakes decision (Yamazaki and Rimal, 2026).

Finally, collection is not integration. Kim and Han found that most multimodal studies gathered streams in parallel, one aligned facial affect, gaze, and face detection after the fact, and none fused its inputs live while

a learner used the system (Kim and Han, 2026). A page of synchronized channels can look like a model of the learner when it is only a recording.

Ethics of sensing learners

Consent is weakened by institutional power. A student who must attend class or sit an exam cannot freely refuse a camera or a wearable. Demographic attributes may not even be volunteered: DIPSER's gender, age, and ethnicity labels were inferred from imagery by computer-vision models rather than supplied by participants (Fragkiadakis et al., 2026). Inferring who someone is, in order to test whether a model treats them fairly, is itself a profiling act.

Biometric data is not ordinary analytics data. EEG, EDA, and heart-rate variability are health-adjacent and, in many jurisdictions, special-category data. They can reveal sleep, stress, and medical conditions beyond anything a course needs. A gaze-informed system for children drew a privacy objection from a parent even in a small pilot (Wu et al., 2026).

Function creep is the normal path. Wellbeing monitoring becomes risk flagging, and risk flagging becomes grading evidence. Corbin and colleagues show the assessment version of this drift: once physical exclusion fails, inspection moves from artifacts to bodies, and students must prove their glasses are corrective and their devices therapeutic (Corbin et al., 2026).

Fairness failures cluster on bodies that differ. Face-based attention estimation depends on skin tone, eyewear, and lighting. Gaze-based attention penalizes learners who avoid eye contact, including some autistic and neurodivergent students. Pose-based proctoring flags tics, stimming, and cultural movement norms. The proctoring study does not test whether flagged posture corresponds to misconduct, or whether the detector treats students with disabilities or cultural differences in gaze fairly (Arif et al., 2026). Regulation is not a fix here; it is a way of laundering the error into a rule.

Fairness claims need subject-level evidence. A gender-targeted regularizer cut the validation MAE gap from 0.02 to 0.005, then increased both the gap and worst-group error on held-out subjects (Fragkiadakis et al., 2026). Reporting a single split as proof of fairness is a design failure with an equity cost.

Privacy can be designed in. TutorLoop ran WebGazer client-side so raw gaze never left the browser (TutorLoop, 2026). That choice shows that some of the cost is architectural rather than inherent. The harder question is whether the inference should exist at all.

Common Misconceptions

"Eye tracking tells you where attention is." It tells you where the eyes point. Gaze can rest on a slide while the learner thinks about something else, and it can leave the screen for reasons unrelated to attention. TutorLoop's attention measure correlated with learning at $r = 0.017$, which is close to no relationship at all (TutorLoop, 2026).

"A physiological signal is a direct readout of a mental state." EDA indexes sympathetic arousal, and heart-rate variability indexes autonomic recovery. Neither distinguishes stress from effort from excitement. A model that predicts exam grades from EDA, movement, and skin temperature has learned the body's arousal signature, not the student's understanding (Yamazaki and Rimal, 2026).

“High classification accuracy means the system detects the state.” Accuracy depends on the labels, the split, and the base rate. EEG familiarity prediction fell from 0.9853 to 0.6038 F1 when validation respected trial boundaries (Nanayakkara and Halloluwa, 2026). Proctoring’s 99.56% describes a bespoke labeled scenario set, not live examinations (Arif et al., 2026).

“Engagement is one thing, so one score can represent it.” The construct has three strands, and a sensor reaches mostly the first. E3Sense found learners defined it through cognitive, behavioral, and emotional indicators in different proportions, and those definitions changed prediction (Anupkrishnan et al., 2026). A single number hides which layer was measured.

“If the model is fair on the validation split, it is fair in the classroom.” A regularizer that equalized validation error across gender groups made the held-out gap worse (Fragkiadakis et al., 2026). Fairness is a property of a deployment, not of a checkpoint.

AI Avatars and Synthetic Instructors

> **AI Avatars and Synthetic Instructors** — human-looking AI systems that occupy a teaching role, whether as a recorded lecturer, a spoken tutor, a pedagogical agent, a simulated patient or student, a role-play partner, or an examiner. The category is defined by a face and a voice standing in for a person, not by a single technology. That surface is what makes these systems engaging, and it is also where their distinctive problems concentrate: Trust attaches to identity cues, realism does not track effectiveness, and learners may not know a human is being simulated.

Questions to Consider

- If a lecture video is presented by a face you later learn was synthesized from your instructor's likeness, what changes for you — the content, your sense of who taught it, or nothing at all?
- A simulated student that is fluent, cooperative and never derails the lesson is easy to talk to. What has that rehearsal prepared you for, and what has it quietly left out?
- Would you want to be told before an encounter that the patient was generated? How would finding out afterward change what you take from the session?
- Which is the greater integrity risk: a learner deceiving an AI examiner, or an AI examiner misreading a learner?
- Peer role-play is free, familiar and socially demanding. What would an avatar have to add for you to choose it instead?

Introduction

An AI avatar is a rendered or animated human representation driven by a model; a synthetic instructor is that representation placed in a teaching role. The two are not the same as an agent. Theelen et al. (2026) separate representation from Learner Agency: the avatar is what a participant sees, while the actor behind it may be a peer, a simulation specialist, a script, a rule-based system, or an LLM. Two identical virtual students can therefore offer entirely different encounters.

This page is organized by role: which role the synthetic human occupies, what evidence exists for it, and what the surface does to the learner's relationship with the system. The literature below spans lecture video, tutoring, clinical simulation, teacher rehearsal, role-play and assessment.

Six roles a synthetic human can occupy

Instructor on screen. A cloned presenter delivers recorded video. In a large online undergraduate course, Tomlinson et al. (2026) rendered three domain-tailored variants of each topic with a HeyGen avatar cloned from the instructor, reviewed before publication, and pushed to the LMS.

Tutor or pedagogical agent. ELEVATE builds a 3D avatar tutor that runs entirely on local hardware, with a teacher-facing layer controlling persona, voice, stance and pacing. ACLIME describes the same role in immersive media: an agent that guides, questions and explains.

Simulated patient or client. SOPHIE 2.0 offers 24 browser-based clinical scenarios with a talking avatar patient. Riachi et al. (2026) apply the pattern to Acceptance and Commitment Therapy, scoring trainee fidelity turn by turn.

Simulated student. Hauk et al. (2026) gave 21 preservice teachers a ten-minute voice conversation with "Marco", a lower-secondary student who makes a disparaging remark about immigrants.

Role-play partner. REMind has children puppeteer a robotic avatar to rehearse bystander intervention. ACLIME calls this the second interaction mode: an agent holding a defined role for situated dialogue.

Assessment interlocutor. The SOPHIE judge scores transcripts against a communication rubric. Tamme et al. (2026) propose a voice agent that interviews students about a course instead of administering a written survey.

What the evidence supports, role by role

The evidence is strongest where the synthetic human is a *partner in practice* and weakest where it is a *stand-in for learning*.

For recorded instruction, the outcome measured is preference, not achievement. Across two offerings and 493 respondents, AI-generated personalized videos outranked non-personalized human-recorded ones (mean rank 2.26 versus 2.69, $p < .001$). The highest-ranked condition, human-recorded personalized video, never existed, so that ranking mixes experience with imagination. The authors report objective learning outcomes as forthcoming.(Students prefer personalized, AI-generated educational videos over non-personalized, human-recorded videos)

For tutoring, the evidence is engineering feasibility. ELEVATE reached roughly five to six seconds to first audio on consumer hardware by streaming speech, which masked most perceived latency. No controlled user study was run, so effects on learning and Help-Seeking remain open.(ELEVATE: Designing Human-Centered GenAI Virtual Tutors for Scalable and Inclusive Education)

For clinical communication, the evidence is the most developed and still stops short of transfer. SOPHIE's judge, reading transcripts alone, reached Pearson 0.759 and ICC(A,1) 0.746 against the consensus of human raters — inside the spread of individual humans rather than outside it. In a remote study of 59 clinicians and students, 92% found it engaging and 83% judged it clinically relevant. Scores rose between two encounters, but with no control arm that rise cannot be attributed to the training.(Scalable AI-based clinical communication training and automated assessment)

For simulated students, the evidence concerns interaction quality rather than outcomes. Hauk's participants rated the dialogue clearly functional ($M = 5.37$) and only moderately authentic ($M = 3.71$), a split the transcripts reproduced at 87.1% versus 37.4% coverage. The avatar carried the challenge work, at 51.1% of its text, while teachers elaborated and justified. Twenty-one volunteers in one program, one session, no comparison with live role-play.(Authentic and functional dialogue with AI-based student avatars: Evidence from a practice-based teacher education program)

For role-play, REMind reports a significant pre-to-post gain in children's perceived Self-Efficacy for defending, with better-calibrated beliefs about whether confronting a bully stops it. That is 18 children aged nine to ten in a play-testing context, which supports promise rather than sustained behavior change.(Play-testing REMind: Evaluating an educational robot-mediated role-play game)

For assessment, the SOPHIE judge is the clearest result and the voice interviewer is the least. Tamme's proposal reports a technical pilot and data not yet formally analyzed; every claim about what voice elicits remains a hypothesis.(Voice-Based AI Feedback in Higher Education: A Field Study on Quality and Actionability)

Trust travels through the face

A face is not a neutral container for pedagogical content. In two experiments totaling 396 participants, Anthis and Kyriakidou-Zacharoudiou (2026) found that avatar identity cues shaped both evaluation and enacted uptake. White avatars, and Asian male avatars in STEM contexts, were rated more credible and competent. Older Black female avatars faced compounded penalties across every measure. Participants adopted guidance more readily from avatars matching their racial ingroup or their stereotype of expertise.

Two details make this a design problem. Domain moderated the effect: STEM and procedural tasks amplified bias, while reflective and interpersonal tasks attenuated it. And the bias operated on behavior, not only on stated attitudes, which means self-reported trust would have missed it. The authors recommend stylized or less anthropomorphic avatars, rotating diverse avatars across tasks, and evaluating uptake rather than satisfaction.(Face value: How avatar identity shapes epistemic trust in AI-mediated learning)

Authority also arrives through the body. ELEVATE's designers warn that body and voice amplify a tutor's authority. They recommend that the avatar signal uncertainty and invite verification against notes or textbooks.(ELEVATE: Designing Human-Centered GenAI Virtual Tutors for Scalable and Inclusive Education) SOPHIE adds a complication: behind the same avatar, a model previously judged more human-like lost that advantage, and communication performance was identical across backends (0.437 versus 0.438). Human-likeness belonged to the interaction — voice, latency, turn-taking — not to the model. (Scalable AI-based clinical communication training and automated assessment)

The counter-evidence is that students can be taught to withhold the human frame even when a prompt supplies it. Stillman et al. (2026) asked 654 writing students whether the chatbot felt like a tutor, a collaborator or something else, and only about half (51.7%) took either anthropomorphic option. Students named it a tool or a program, compared it to a robot or a computer, or invented metaphors such as a vending machine of feedback that dispenses text for data. The authors treat that refusal of the human frame as the literacy outcome, which dates the effect to instruction rather than to the interface.

Presence, realism and the uncanny

Realism is not a ladder. ACLIME treats behavioral realism as the decisive predictor of social presence and warns that higher visual fidelity risks the uncanny valley, where a nearly human agent triggers sudden rejection. It also prices the trade-off: immersion and agent realism raise extraneous cognitive load, while interaction can lower intrinsic load through collective working memory. Its headline caution is blunt — roughly 42% of VR headset users report cybersickness, and after-effects run from about ten minutes to several hours.(Learning with pedagogical agents in extended reality: A conceptual research-based framework of agent-centered learning in immersive media environments (ACLIME))

Practice studies mostly support the modest version of this claim. Hauk's authors read moderate authenticity as fidelity fit for function. A dyadic, voice-only rehearsal stabilizes routines for novices, and peer dynamics

and nonverbal cues can be added later.(Authentic and functional dialogue with AI-based student avatars: Evidence from a practice-based teacher education program) In SOPHIE, 47% of participants still found it hard to feel real empathy toward an AI patient, even though 66% found talking to one less stressful than talking to a person.(Scalable AI-based clinical communication training and automated assessment)

Learners do not uniformly want more realism. In TriKoNet's exploratory study, students unanimously rejected photorealistic representation. They used a modular design space to author their own role concepts instead of adopting a supplied persona.(TriKoNet: The Trivalence Model of Potential Co-Creativity in Socio-Technical Networks) ELEVATE notes that embodiment is a barrier for some learners, such as those with sensory sensitivity or discomfort with anthropomorphic agents, making avatar configuration a requirement rather than a preference.(ELEVATE: Designing Human-Centered GenAI Virtual Tutors for Scalable and Inclusive Education)

Consent, disclosure and deepfake risk

Across these accounts, disclosure appears as a design decision rather than a measured variable. Hauk's scenario sat on the edge of hate speech, and its safeguards were procedural. The design included orientation, moderation guidelines, continuous instructor monitoring, an option to stop immediately, structured debriefing, and pseudonymized aggregate analysis.(Authentic and functional dialogue with AI-based student avatars: Evidence from a practice-based teacher education program) Theelen's framework asks that learners and teacher educators know which parts of a simulation are controlled by people, scripts or AI, and treats that transparency as a condition of defensible adaptation.(Classroom simulations for social-emotional learning and inclusive teacher education: a four-layer conceptual framework in the age of AI)

The harder question is whether simulating a person is itself a small deception. A learner who believes a struggling patient is real may invest care a disclosed simulation would not elicit, then feel misled once told. Hauk's moderate authenticity ratings suggest participants were not fooled about the avatar's nature; SOPHIE's 47% empathy finding suggests some were engaged despite knowing. Neither study tests disclosure directly.

Disclosure also has a production side. Tomlinson's pipeline cloned the instructor's likeness and voice. A subset of students raised principled objections to GenAI — environmental cost, labor, automation, integrity — that better rendering would not answer.(Students prefer personalized, AI-generated educational videos over non-personalized, human-recorded videos) An instructor's consent to being cloned is a separate question from a student's consent to being taught by the clone, and no study here measures either.

Deepfake literacy is the reverse face of the same capability. In an Australian secondary sample of 199 students, males were significantly more likely to have created or shared deepfake content (23.2% versus 10.0%). The authors argue for safety education aimed explicitly at them.(Gender Differences in AI Literacy Workshop Outcomes and Deepfake Engagement) Once an institution can generate a convincing instructor, a convincing patient or a convincing student, verification of who is speaking becomes an Academic Integrity issue as much as a literacy one. Oral defenses and process evidence, which ELEVATE's authors recommend once on-demand tutoring is available, address the same underlying problem.(ELEVATE: Designing Human-Centered GenAI Virtual Tutors for Scalable and Inclusive Education)

The honest state of the evidence

Almost every study here is small and short. Hauk has 21 volunteers and one session. SOPHIE has 59 completers and no control arm. The psychotherapy evaluation has two psychologists, about 90 minutes each. The PBL pilot has 26 students and one case. ACLIME and Theelen are conceptual frameworks, and TriKoNet's base is eight groups in single sessions.(Using Generative AI to Simulate Patient History-Taking in a Problem-Based Learning Tutorial: A Mixed-Methods Study)(Toward Accessible Psychotherapy Training Using AI-Driven Interactive Patient Avatars)(Learning with pedagogical agents in extended reality: A conceptual research-based framework of agent-centered learning in immersive media environments (ACLIME))(Classroom simulations for social-emotional learning and inclusive teacher education: a four-layer conceptual framework in the age of AI)(TriKoNet: The Trivalence Model of Potential Co-Creativity in Socio-Technical Networks)

The large samples concern attitudes and preferences — 396 participants on avatar identity, 493 respondents on video preference — and both are convenience or single-course populations. No study in this set demonstrates that a synthetic instructor produces better learning than a human one. The defensible claim is narrower: these systems can approximate a practice encounter, can be scored against human raters with acceptable agreement in one domain, and can shift how learners evaluate the source of instruction.

That narrowness matters. Theelen's authors put it directly: fluency and a sense of presence are not validity evidence.(Classroom simulations for social-emotional learning and inclusive teacher education: a four-layer conceptual framework in the age of AI) Sounding like a teacher clears the easiest bar in the room.

Common Misconceptions

"A more realistic avatar teaches better." Realism and effectiveness came apart wherever both were measured. SOPHIE's two backends produced identical communication scores behind the same avatar, and TriKoNet's students rejected photorealistic personas outright.

"If the avatar is convincing, learners will treat it as a person." Medical students interviewed a genAI patient as a searchable question base, mostly with closed-ended queries, even while rating the experience highly.(Using Generative AI to Simulate Patient History-Taking in a Problem-Based Learning Tutorial: A Mixed-Methods Study) Conviction and interaction style are separate outcomes.

"Synthetic instructors are one technology, so findings transfer." A cloned lecturer optimizing for preference, a tutor for latency, and a patient for clinical fidelity are different artifacts with different failure modes. Evidence from one role does not license claims about another.

"Avatar appearance is cosmetic." Identity cues changed credibility ratings and actual uptake of guidance, with penalties compounding for older Black female avatars.(Face value: How avatar identity shapes epistemic trust in AI-mediated learning) Configuration is a pedagogical and equity decision.

"A simulated patient is a standardized patient, minus the cost." Trainee psychologists found their virtual patient cooperative and already therapy-advanced, an "ideal" case that under-represents behavioral inflexibility.(Toward Accessible Psychotherapy Training Using AI-Driven Interactive Patient Avatars) Cost falls; case validity does not automatically follow.

Human-in-the-Loop

> **Human-in-the-loop** — the design pattern in which educational AI systems strategically interleave automated generation with human expert judgment, preserving pedagogical quality and safety while scaling production. Rather than fully automating assessment, feedback, or instruction, HITL keeps a human (instructor, subject-matter expert, or learner) in the decision loop where their judgment has the highest marginal value — for evaluating quality, adjudicating edge cases, and protecting learner agency and safety. The central design question is not *whether* to include humans, but *where* in the pipeline their oversight is most valuable and least replaceable.

Questions to Consider

- The central HITL design question is not whether to include humans, but where in the pipeline their judgment is most valuable. In an AI assessment or feedback system, at what point would you insist a human stay in the loop?
- Studies of AI question generation found computers handle clarity and validity well but humans are still needed for meaningful distractors and good feedback. Why might some parts of educational judgment resist automation?
- One evaluation found three LLMs gave inconsistent, insensitive student-support recommendations — concluding human judgment is still needed before AI advises on students. When an AI 'recommends' support for a struggling student, what could go wrong if no human reviews it?
- The page suggests humans and algorithms catch different kinds of problems — automate what is precisely verifiable, preserve judgment where nuance is irreplaceable. Where in your own practice is the boundary between the two?
- Keeping a human in the loop is framed as protecting learner agency and safety, not just quality. How might full automation subtly change students' sense of who is responsible for their learning?
- If AI becomes more autonomous, HITL oversight is described as a core safety guardrail. At what level of AI autonomy would you feel uncomfortable — and what does that discomfort tell you about where oversight belongs?

Introduction

HITL is a response to the limits and risks of fully autonomous AI in education: automated systems can generate at scale but lack the contextual, ethical, and pedagogical judgment that instructors and experts bring. Two recent implementations illustrate distinct architectures: - **Human-in-the-loop is insufficient if the human only approves.** Rienties, Divjak and Law (2026) argue that meaningful agency requires the capability to understand, contest, redesign and sometimes reject AI-supported recommendations, not merely to approve decisions shaped elsewhere.

Prescriptive support is a domain where human oversight is increasingly argued to be non-optional. López-Pernas et al. (2026) tested whether three LLMs could recommend student-support plans from Learning Analytics indicators and found limited sensitivity to need and sharp cross-model inconsistency —

concluding that human-in-the-loop judgment is still necessary before Large Language Models (LLMs) prescriptive advising can be deployed safely and ethically.

Withholding a system's preferred answer is protective rather than corrective: in a multi-agent debate that never revealed a recommended position, detrimental switching to an incorrect AI answer fell from 42.0–60.5% to 5.7–8.2%, while adoption of correct advice also fell (Tuo et al., 2026).

A third architecture places human judgment *upstream* of the model rather than at its output. In Lee, Atif & Kang's (2026) study of learner-question classification, three doctoral-level experts governed the whole pipeline: they refined the operational definitions for each Constructivism role, labeled independently until Fleiss' kappa rose from 0.60 to 0.83 after discrepancy resolution, and validated the back-translated and paraphrased items used to balance the training set.

CODE-GEN: Human-in-the-Loop MCQ Generation

Duan et al. (2026) built a RAG (Retrieval-Augmented Generation)-based agentic system with two agents: - **Generator Agent** — Produces multiple-choice coding questions aligned with course learning objectives - **Validator Agent** — Assesses quality across seven pedagogical dimensions

Evaluation: 6 SMEs judged 288 AI-generated questions. Human-validated success rates: **79.9%–98.6%** across dimensions.

AI-Strong Dimensions (low human burden): - Question clarity, code validity, concept alignment, correct-answer validity

Human-Required Dimensions (high human burden): - Pedagogically meaningful distractor design - High-quality explanatory Feedback

Strategic insight: Human effort should be concentrated where instructional judgment is irreplaceable; computational verification can be fully automated.

MAIC: Human-in-the-Loop Script Generation

Yu et al. (2024) deployed a multi-agent classroom (Teacher Agent, TA Agent, classmate archetypes) at Tsinghua University with >500 students and >100,000 learning records. Human instructors participate in script generation and oversight, ensuring that mass-scale AI augmentation does not displace pedagogical expertise.

PedaCo: Dual Gatekeeping for AI Video Generation

Kim, Baek, and Kwak (2026) extend HITL to AI-generated instructional video via **PedaCo** (Pedagogical Co-creation), a pipeline with two complementary gatekeeping layers that instantiate *principled resistance* grounded in Mayer's Cognitive Theory of Multimedia Learning (CTML). The **first layer** places the human at the script stage: an LLM drafts a script, an AI reviewer flags potential CTML violations (e.g., "Scene 3 introduces technical terms without prior explanation"), and the educator decides to accept, revise, or regenerate. The **second layer** runs automated metrics post-synthesis on coherence, redundancy, temporal contiguity, modality, and image quality, which the educator reviews. In a within-subject study (23 educators), the review-based approach improved every CTML principle (mean rating 3.07 → 3.86, $p<.01$), with educators

rating production efficiency at 4.26/5 — friction perceived as productive, not burdensome. The design principle echoes the knowledge base's HITL synthesis: humans and algorithms catch *different* kinds of problems, so the most effective systems automate where computational verification is precise (temporal synchronization) and preserve human judgment where pedagogical nuance is irreplaceable (tone, audience fit).

Placement can matter more than presence: practitioners rated a Social Story authoring tool highly usable (SUS 86.8) yet reported that review came too late, because cultural and clinical constraints set before generation — an abaya instead of Western streetwear — are harder to recover by editing output afterward (Enkhjargal et al. (2026)).

Why HITL matters in the AI era

Human-in-the-loop design has become central to the knowledge base's agentic AI and responsible AI use discussions for several converging reasons: - **Pedagogical safety.** Pedagogical Safety requires that AI with real instructional authority retains human oversight, so errors, biases, or harmful outputs are caught before they reach learners. This is especially important for autonomous agents that proactively pursue goals. - **Oversight is rare in practice, not just in theory.** Wang et al. (2026) found robust embedded governance and human-in-the-loop oversight were rarely exhibited across 474 educational agentic-AI systems, even as single-task autonomy and multi-agent collaboration grew — the gap between the design principle and deployed practice. - **The critical question is how the loop is made actionable, not how much humans participate.** A Learning Sciences view argues that organizing learning around data capture, computational interpretation and probable response makes pedagogical action depend on what systems can detect and act upon, and that alerts and engagement classifications interpret the learner before any teacher or student acts (Pande (2026)). - **Validity and quality control.** HITL is a quality gate for automated assessment and generation — humans adjudicate where automated scoring is unreliable (see LLM essay grading research) and validate generated items. A PRISMA-guided systematic review of 42 grading and feedback studies (2023–2025) reaches the same conclusion explicitly: LLMs match human raters on short, well-structured tasks but cannot fully replace human judgment on complex, open-ended, or subjective work, and the highest grading effectiveness is achieved in hybrid systems that combine AI-driven grading with teacher oversight and verification (Can ChatGPT Replace the Teacher in Assessment? A Review of Research on the Use of Large Language Models in Grading and Providing Feedback). Falahat et al. (2026) show concretely where that boundary falls: ChatGPT-5 matched faculty on objective pharmacy-exam items (CCC 0.935–1.000) but was unreliable on short-answer and essay items even when given a rubric, leading the authors to recommend hybrid grading with human review for complex, subjective, or high-stakes assessment. - Repetition is not a substitute for that oversight: regrading identical submissions on five different days, the same model reproduced its own results at only Krippendorff's alpha 0.625, with variation concentrated in the middle grades and A and F absent from the five-session counts (Brevik et al. (2026)). - **Learner agency.** Keeping a human in the loop preserves Learner Agency and supports Self-Regulated Learning, countering the over-reliance that fully autonomous assistance can induce.

- **Students put the human at the high-stakes end themselves.** Among 93 undergraduates, 81.7% preferred human scoring for a final paper worth 40% of the grade, 75 of 93 wanted AI to assist rather than replace graders, and 69 wanted AI scoring always human-reviewed (Yildirim-Erbasli et al. (2026)).

- **Trust and calibration.** Transparent human oversight supports Trust Calibration — learners and instructors know a qualified human stands behind the system.
- **Criteria visible before review raise agreement.** Coscia et al. (2026) found that surfacing trustworthiness metrics to reviewers as they compared LLM responses lifted inter-rater agreement from Krippendorff's alpha 0.3987 to 0.4931, while adding further measures added cognitive overhead without return.
- **Bounded agency as an architecture, not a disclaimer.** Ilieva et al.'s (2026) AGAI-HE framework for agentic learning support builds supervision into the model itself, as a third layer alongside the pedagogical-workflow and agentic-support layers: it defines acceptable AI use, pedagogical boundaries, Privacy rules, disclosure requirements, source verification, instructor checkpoints, integrity mechanisms, and final human accountability, and requires every agentic function to trace to a learning requirement, assessment purpose, or governance control. It is a concrete instantiation of the principle that HITL is a system-design property rather than a policy statement — and the authors' 130-student perception study is a reminder that adding agentic orchestration under that oversight did not, by itself, register as better learning support than a chatbot.
- **How often the human looks is itself a design decision.** Venetsanos (2026) separates the *frequency* of oversight from its placement: high-frequency HITL, reviewing every AI output before it reaches students, buys quality control, rapid error detection, accountability and ongoing calibration but can cancel out the efficiency that motivated automation and bottleneck peak marking periods; low-frequency HITL, spot-checking samples and reviewing only flagged cases, scales and shortens turnaround but risks errors propagating undetected across submissions, weakens accountability, and creates an equity problem if some students receive more thorough human review than others. Rather than prescribing a universal answer, the framework requires the trade-off to be made explicitly against disciplinary error tolerances, whether the assessment is formative or summative, cohort size and institutional resources — and sets a default in the opposite direction from the usual efficiency argument: begin with high-frequency oversight and scale it back only when substantial evidence demonstrates acceptable reliability, security and fairness, so the burden of proof rests on showing that *less* oversight is safe. The paper also warns that the principles behind such oversight may shift staff effort rather than reduce it, leaving net efficiency gains an open empirical question.
- Deployed human oversight can mean approval routing rather than quality judgment: in a hybrid query system the acceptance field encoded only whether the resolver differed from the asker, and no measure assessed answer quality Gupta et al. (2026).

Where HITL appears in the knowledge base's research

- **Automated assessment and grading:** HITL systems combine AI generation/scoring with human validation across short-answer grading (Confidence Estimation in Automatic Short Answer Grading with LLMs), self-explanation assessment (Exploring the Effectiveness of Using LLMs for Automated Assessment of Student Self Explanations in Programming Education), and essay scoring (PsyScore: A Psychometrically-Aware Framework for Trait-Adaptive Essay Scoring and ZPD-Scaffolded Feedback). Cvengros & Kortemeyer instantiate this in high-stakes, handwritten

general-chemistry grading: because a Multimodal AI LLM's reliability varies by response format (textual and chemical-reaction answers are reliable while drawing and graphing score worse than random) and false positives go undetected by students, they convert raw AI scores into a selective accept/deferral policy using confidence filters — partial-credit thresholds, an IRT-based risk threshold, and problem-type exclusion — deferring uncertain and graphical items to humans, an approach the authors tie to regulatory frameworks that designate AI in educational assessment as high-risk and mandate documented human oversight.

- **Feedback systems:** mandate documented human oversight.
- **Operational HITL scoring in a national assessment (2026):** Curi et al. (2026) instantiate HITL at institutional scale in Uruguay's Acredita EB exam. Because the LLM scorer's errors are systematically conservative (under-grading), the workflow uses a decision-point logic that routes human review to exactly the candidates whose pass/fail outcome depends on the Writing section — AI-marked passing responses are accepted with confidence, while AI-marked failures (15.3–16.5% of cases) are verified by expert raters, cutting full-scoring workload by ≥50% with a residual AI-error pass risk of only 0.2–0.6%. This is HITL as a resource-allocation strategy: humans adjudicate precisely where AI's conservative bias would otherwise alter high-stakes outcomes.
- **Deriving the deferral threshold from the rubric's own resolution (2026).** Cruz et al. (2026) set the AI–instructor tolerance at 0.5 points — the largest discrepancy that cannot move a submission across an anchor band — and escalated outliers at 0.8 points, sending 11 of 362 submissions (3.0%) to human review before feedback was released.
- **Agreement between annotators is not human ground truth.** Bernado et al. (2026) push model annotation into the audit layer without ever validating it against human gold labels, leaving cross-model agreement (median 0.401) a proxy for assertion quality that shared model errors can survive. Their design keeps oversight diagnostic rather than decorative: because the intermediate judgments are explicit, a reviewer can see which behaviors fired and separate a misread behavior from a rule that encodes the construct badly.
- **Feedback systems:** human-in-the-loop feedback design appears in collaborative feedback systems and confidence-aware short-answer grading.
- **Classroom collaboration support.** CoBi keeps the teacher as the reviewing human in an AI system that detects uplifting small-group discourse: teachers explicitly favored pre/post-action review over live real-time display that would put them "on the spot," and the system's classroom-level (rather than individual) aggregated feedback is precisely what lets it navigate the tension between Privacy, surveillance, and student Learner Agency.
- **Question and content generation:** beyond CODE-GEN, HITL guides question generation for assessment and Scaffolding (CODE-GEN: A Human-in-the-Loop RAG-Based Agentic AI System for Multiple-Choice Question Generation, From Evaluated Models to Evaluation Aids: A Multi-Evidence Study of LLM-Based Difficulty Calibration for Programming Examinations).
- **Agentic and multi-agent systems:** as AI becomes more autonomous, HITL oversight is a core design guardrail (Agentic AI and Pedagogical Best Practice: The Tension Between Automation

and Learning, Beyond Access: Guided LLM Scaffolding for Independent Learning in Undergraduate Statistics).

- **Routing by decision consequence, not model uncertainty (2026).** A 2026 operational study of Uruguay's Acredita EB national accreditation test (two editions, roughly 5,000-6,000 candidates each) shows what human-in-the-loop design looks like when it is driven by decision consequences rather than by model uncertainty. A GPT-5 scorer agreed with expert raters on 60-80% of the 15 rubric items but was systematically conservative, producing human-pass/AI-fail discrepancies in 15.3% (2024) and 16.5% (2025) of pass/fail comparisons and almost never the reverse. The framework therefore accepts AI-passing results at face value and routes every AI-failing result that could change a candidate's outcome to expert review — after first skipping candidates whose pass/fail cannot depend on the writing section — cutting responses needing full human scoring by at least 50%. A second 2026 design draws the boundary from the other side: in a multi-agent AI standardized-patient platform (Yang et al.), human oversight is reserved for what AI is judged unfit to decide, with faculty and human standardized patients supplying contextual interpretation, remediation and readiness judgments, and the system explicitly not permitted to determine clinical competence autonomously.
- **Research instrumentation: humans validate labels rather than scores.** Learning-science and computer-science coders judged LLM-generated behavior segments on a synchronized timeline at $\kappa = 0.703$, and their disagreements became the study's own error analysis (Fonteles et al., 2026).
- **The model summarizes and the researcher labels.** A collaborative-modeling study used GPT-3.5-Turbo to write a task-context-aware summary of each of 394 discourse segments, had researchers verify every summary and code them to $\kappa \geq 0.7$, and trained the detectors on those labels, so the model never made the judgment itself. Oversight then moved outward: four experienced teachers reviewed a labeled segment, three recognized the behaviors, and one argued that two labels on one segment obscured what the students were doing, a usability objection the authors recorded rather than resolved (Zhang et al., 2026).
- **HITL as an architecture for a whole discipline, not one workflow.** Zhai et al. (2026) specify four interlocking layers, data infrastructure, model development, pedagogical interface and human governance, held together by three principles: human oversight and agency, co-adaptive intelligence, and contextual responsiveness.

Synthesis

Human-in-the-loop design is not merely a safety measure—it is a **resource-allocation strategy**. The frontier question is not *whether* to include humans, but *where* in the pipeline their judgment has highest marginal value. The most effective HITL systems concentrate scarce human expertise where automated systems are weakest (distractor design, explanatory feedback, edge-case adjudication, ethical judgment) and automate the rest — preserving quality, safety, and trust while scaling production. - **Human oversight persists in AI-assisted work.** Systematic-review research found AI automation tools reduced procedural burdens (e.g. screening) but interpretive decisions still required substantial human oversight; andragogy research makes human-in-the-loop (shared mental models, co-creation) a core AI design principle. - **Human-in-the-loop at institutional scale.** Qin (2026) describes how Lingnan University developed a human-in-the-loop

educational model that foregrounds ethical reasoning, critical judgment, and social responsibility while democratizing GenAI access. The model positions humans as the locus of judgment and values even as AI is embedded across the curriculum — a concrete institutional instantiation of human-in-the-loop principles in higher education. - **Learners as the human-in-the-loop of their own tutoring.** Value Sensitive Design with community college students produced a full family of learner-facing HITL features for an ITS (control over re-assessment and review, personalized goals/pace, bookmarking for review, confirming confidence over mastery, and an AI-assistance involvement-level control). This positions the student as an active controller of the tutoring loop rather than a passive consumer of adaptive decisions. The study also found instructors divided on whether such learner control could undermine the integrity of the system-guided learning path — an instance of the broader resource-allocation question of where human (learner vs. teacher) judgment adds most value. - **Escalation from AI to expert is a human-in-the-loop move.** The SCAN framework assigns tasks to four generative-AI modes by learner distance, and reads passive engagement inside a correctly assigned AI task as a mis-skilling signal to shift the learner from AI to expert assistance, with a human as epistemic auditor (Tsim et al. (2026)). - **Oversight of AI adoption advice.** Because conversational AI systems consulted by skeptical users may be predisposed to encourage adoption, human oversight and independent evaluation are essential. An audit showing most frontier models redirect skeptical rural K-12 staff toward engagement underlines the need for transparent, auditable AI advice rather than uncritical reliance.

How strong that safeguard is depends on Automation Bias. A merely formal opportunity to accept or reject does not place the human inside the production of the judgment if they defer to the output, and the corpus has not run the blinded comparison that would show how often they do.

Common Misconceptions

- **“Showing the system’s recommendation helps the human supervise it.” Withholding a system’s preferred answer is protective rather than corrective**: in a multi-agent debate that **never revealed a recommended position**, detrimental switching to the AI’s answer **dropped**. Disclosure invited deference; withholding supported judgment.
- **“Human-in-the-loop must mean one human, one decision.”** A multi-agent classroom of Teacher Agent, TA Agent and classmate archetypes was deployed at Tsinghua University with **more than 500 students and more than 100,000 learning records**. Supervision scales through the arrangement, not by multiplying supervisors.
- **“Reviewing AI output is intuitive.”** In a **within-subject study with 23 educators**, a review-based approach **improved every CTML principle (mean rating 3.07 to 3.86, $p < .01$)**, with educators rating production efficiency favorably. Review is a skill that improved under a structured method.

Learning Analytics

> **Learning analytics** — the measurement, collection, analysis, and reporting of data about learners and their contexts for the purpose of understanding and optimizing learning. AI has transformed learning analytics from descriptive dashboards to predictive and prescriptive systems.

Questions to Consider

- Most people assume collecting more learning data automatically improves education. The page argues analytics become meaningful only when they feed back into an intervention — otherwise they merely describe or flag without changing learning. Where have you seen data collected that never led to any action?
- Imagine a dashboard tells you a student is ‘at risk’ — a prediction. What separates that from genuinely actionable guidance that a teacher or institution can actually carry out? The page suggests prediction alone is not enough.
- The page notes AI has moved learning analytics from describing what happened to predicting what will happen and prescribing what to do next. Which of these three generations have you experienced, and what was missing in the others?
- In one study, three different AI models produced sharply different support plans for the same student data, and the links between analytics indicators and recommended help were mostly weak. What does this suggest about trusting an AI’s advice at face value?
- Learning analytics sits in a privacy tension: the more granular the data, the more revealing — and the more powerful the intervention. Where would you draw the line on what is collected about you or your students, and who should decide?

Introduction

AI-enhanced analytics

- **Predictive analytics:** Machine learning on learner interaction data predicts outcomes — from at-risk identification to knowledge state estimation.
- **Validation matters as much as prediction.** Schuetze, Yan, and Carvalho (2025) show that predictive knowledge-state models (BKT, BKT-with-Forgetting, AFM) look accurate when fit retroactively to a full session history, yet under **time-based cross-validation** — predicting the next session from prior ones, how analytics are actually deployed — they overestimate learner performance, miss spacing/forgetting dynamics, and can mis-order practice conditions. The caution for analytics: retrospective fit can mask poor forward predictive validity on longitudinal data, so indicator and dashboard models should be validated walk-forward.
- **Validate the item-attribute mapping behind the estimate.** The Q-matrix linking items to attributes is an assumption, not data: rejected entries for 14 of 918 analytical-thinking items, once

corrected, cut a spurious knowledge-state pattern from 14.2% to 3.8% — so mastery analytics should audit their Q-matrix, not only their predictive fit (Feng & Huang, 2026).

- **Curriculum-anchored predictive analytics:** Pradeesh et al. (2026) estimate knowledge states within Outcome-Based Education by tracing course outcomes directly from LMS interaction and attainment data, using OBE affinity mappings (course–program outcome relations) to structure concept links and a memory-augmented network to model cross-outcome impact — reaching 89.81% AUC and beating DKT, DKVMN, EKT, and SimpleKT on live university engineering data, while staying only competitive (not superior) on general-purpose ASSISTments data.
- **Interpretable progress prediction with an action window:** Zhang, Jeffries & Koprinska (2025) predict module-level student progress in large-scale online programming courses from content-interaction log features, using glass-box decision trees that match black-box accuracy (85–91%) while flagging "No submission" dropout outcomes up to 7–8 days before module deadlines — an explicit, real-time window for intervention rather than a bare risk flag, and an exploratory typology of disengaged-at-risk, disengaged-but-successful, and engaged high-performer profiles.
- **Approval does not predict the engagement pattern.** Trace data from a learner-facing analytics tool in a GAI-supported programming course split 27 students into Deep, Self-Oriented and Peer-Oriented Explorers plus a final-stage Limited Explorers profile, yet favorable perceptions of the assistant did not differ significantly across those profiles (Sun et al. (2026)).
- **Federated, explainable risk modeling across institutions (2026).** Villegas-Ch et al. (2026) extend risk modeling beyond single-institution prediction by training a multitask (performance + dropout) model across simulated institutions via federated learning, so raw student data never leaves each institution. Under controlled heterogeneity (label skew, class imbalance, temporal drift, structural missingness) the model preserves ranking accuracy (OULAD AUC 0.918) and structurally stable feature-importance rankings, yet probabilistic calibration drifts — decoupling ranking performance from probability reliability. For early-warning systems this is a caution that threshold-based interventions may need per-institution calibration, and an argument for evaluating analytics along discrimination, calibration, robustness, and explainability at once.
- **Synthetic-data validation is a prerequisite for privacy-preserving analytics.** A structural check on synthetic versions of four annual study-habit cohorts (117-120 learners over eighteen weeks) found partition descriptors agreeing closely in two of four cohorts while week-to-week variation ran 2.6 to 4.9 times lower without exception (coefficient of variation 0.086-0.152 against 0.399-0.539 for the real cohorts), and only 36% of findings reached on synthetic pilot data were confirmed on the real data across twenty-five validation requests (Inoue & Yasutake (2026)).
- **Engagement analytics:** Engagement measurement and intensity modeling quantify how students interact with AI systems.
- **Completion rates can hide an engagement collapse.** In a group-randomized university trial, a course-integrated AI tutor left homework submission unchanged while platform participation fell sharply — page views by 0.37 standard deviations, active days by 0.51 — so the analytics signal that mattered was the activity the tool displaced, not the completion metric that stayed flat (Liu et al. (2026)).

- **Feedback analytics:** Feedback classification and quality assessment analyze the feedback students receive.
- **Network analysis:** Co-Occurrence Network Analysis and epistemic network analysis reveal interaction patterns.
- **Privacy tensions:** Privacy concerns grow as analytics become more granular and AI-driven.
- **A governance review framework for student data.** LEAGUE proposes six pillars — Lawfulness, Equity, Agency, Governance, Utility, and Ethics by Design — treating FERPA and GDPR compliance as the floor and recommending scheduled reassessment as models drift (Varadaraju & Vijayakumar (2026)).

Sensor and gaze analytics is a second instrument family feeding the same learner models, drawing on eye tracking, EEG, electrodermal activity and heart rate to estimate attention, engagement and cognitive load (Sensor and Gaze Analytics). Its validity and consent problems are steeper than trace data's, because the measurements are biometric and the step from body to mental state is an interpretation.

Model course concurrency, not just sequence. TRACE gives every course in a semester the same positional encoding, and jointly predicting courses and grades cut grade-prediction error to 0.1339 MAE — a 46.4% reduction over a grades-only transformer — on ten years of institutional data (Savala (2026)).

Interaction data is a representation problem before it is a modeling one. Taufer et al. (2026) treat each human-AI exchange as one structured record carrying the computation that motivated the request, the request, the response, the user's feedback and the execution that followed, rather than as an isolated prompt. Across 140 student-assignment pairs in a 35-student deployment, interaction count alone correlated with successfully executed cells at $r = 0.12$, and the same call could be an error recovery, a next step, a concept check or a validation depending on the state around it. Thirty-seven pairs with access produced no interactions at all, so absence of AI use in a log cannot be read as absence of need.

The learning analytics cycle

Learning analytics is canonically framed as a cycle that begins with learner activity producing data, which is processed into measures and indicators that are then translated into **interventions** — and the intervention feeds back into learner activity to close the loop. The intervention step is what distinguishes analytics from mere monitoring or prediction: without it, analytics describe and flag but never change learning. This cycle is the organizing frame for understanding where AI tools (dashboards, feedback generators, prescriptive recommenders) sit in the pipeline and which step they automate.

A learner-facing dashboard is only as good as its reach: in a Hong Kong Grade 9 writing study a prompt classifier reached a macro F1 of 0.757, about a third of the 46 students opened the three GenAI-use dashboards and the group differences in copying and learning-oriented prompting were not reliable (Fong et al. (2026)).

A frequency encoding of qualitative data is an entry point, not a verdict: in a ten-participant study, some instructors read frequency encodings as a productive way in while others warned they obscure rare but critical responses, so the design keeps every aggregate view linked back to verbatim student text (Nguyen et al. (2026)).

From description to intervention

- **The evidence base is not yet intervention evidence.** Synthesizing four studies across student, disciplinary, educator and institutional levels, Rienties, Divjak and Law (2026) find the field dominated by cross-sectional, self-report, discourse-based and expert-judgment designs, and call for intervention research testing causal mechanisms and longer-term, distributional outcomes.

Learning analytics has evolved through three generations in the knowledge base: descriptive (what happened?), predictive (what will happen?), and prescriptive (what should we do?). AI enables the prescriptive layer — analytics that directly trigger instructional interventions. A key frontier is the **actionability gap**: SC2R (Le, Abel & Laforge 2026) shows that prediction alone is insufficient for decision support, and that counterfactual recourse becomes operationally meaningful only when recommendations are semantically feasible and machine-checkable — constrained by timing, budget, immutability, and availability via SHACL validation, rather than merely model-valid. This moves the field beyond risk scores toward recommendations that institutions can actually enact, with human oversight preserved.

A direct empirical test of the prescriptive layer comes from López-Pernas et al. (2026), who asked three LLMs to recommend support plans for 4,500 synthetic student vignettes.

A complementary, teacher-centered test of how analytics reach the classroom comes from Mejia-Domenzain et al. (2026), who designed a learning analytics dashboard (DashED) to communicate ML-derived Self-Regulated Learning profiles to teachers in two blended contexts. Their 100-teacher study shows that the *presentation* of analytics is itself a barrier to action: teachers systematically preferred simpler, more traditional charts (bar plots, pie charts) even when more complex designs (e.g., heatmaps) yielded richer insights, and higher visualization literacy predicted deeper, more detailed interpretation (e.g., more teachers identifying trends in time-series data). For group comparison, teachers favored superposition over juxtaposition and full-information plots over explicit difference encoding. The actions teachers proposed were shaped by the content represented and their Teaching level rather than the plot type — university teachers favored weekly tests and course-level adaptation, while vocational teachers proposed direct, individualized coaching — so the prescriptive step depends as much on how analytics are visualized as on the model. Their finding is cautionary: correlations between LA indicators and recommended support were mostly weak, cross-model recommendations diverged sharply for the same student, and support was frequently allocated regardless of who needed it most. The authors conclude that current LLMs are **not yet reliable as prescriptive models for student support at scale**, reinforcing that the prescriptive step still requires validation, fine-tuning, and human oversight rather than off-the-shelf automation.

The step after the score — who gets support, and whether it was allocated where it was needed — belongs to student support and success, which carries the outreach, referral, and allocation evidence this page's prescriptive layer feeds.

An integrity outcome enters the same predictive layer. Akçapınar (2026) predicts AI-assisted cheating risk from the first eight weeks of Moodle and video-player traces, reaching an AUC of 0.763 with logistic regression, and argues the signal is usable precisely because it arrives before the exam rather than during it. A complementary line targets the *interpretation* of analytics itself. Marques et al. (2026)'s FACTRIA framework organizes the biasing factors behind an indicator - pipeline, institutional, course, and demographic - and a reflection-prompting chatbot raised the sub-factors 11 stakeholders weighed per case from 1.41 to 3.45 (d = 2.15), shifting them from direct readings to conditional ones.

Methods and network analysis

Network methods are core to learning analytics: transition network analysis (TNA) models temporal sequences of learner actions (e.g., the revision and chat loops in chatbot-scaffolded writing), and epistemic network analysis (ENA) maps how codes/constructs co-occur across activity — together revealing the *process* of learning and learner-AI interaction rather than only its product.(Penny: Transition Network Analysis of Learner-Chatbot Interactions in Scaffolded EFL Writing)(Tracing GenAI Literacy: Student-AI Interaction Patterns in Academic Writing)

- **Clustering clickstreams in self-directed model building.** An, Hammock & Goel (2025) combined activity sequence analysis, hierarchical clustering, and Markov chain models on the clickstreams of 315 online learners who built 822 ecological models in VERA, distilling nine fine-grained, transition-based behavioral clusters into three broader patterns (Observation, Construction, Exploration). Their work demonstrates that combining sequence analysis with Markov chain modeling can uncover meaningful behavior in unstructured, self-directed tasks even in the complete absence of demographic or contextual data.
- **LA and GenAI shape learning design differently (2026).** Claassen et al. (2026) used ENA on 11 instructor focus groups to compare how learning analytics versus Generative AI inform Learning Design decision-making. LA discussions centered on contextual information, course-level design, and creative Problem Solving (LA for diagnosing engagement and targeting support), while GenAI discussions centered on assessment design and designing for student self-determination (GenAI for ideation and assessment development). Context and Creativity were central across both — a reminder that analytics inform design only within pedagogical context and instructor autonomy.
- **Talk beats fusion when the construct is social, and the best source is per construct.** Rather than maximizing modalities, a LAK26 comparison of five feature configurations on collaborative modeling segments found text-only embeddings strongest overall (mean ROC AUC 0.650, 95% CI 0.615 to 0.685) against text plus logs (0.613) and text plus logs with a context window (0.623). Logs measured 0.526 alone, near chance for a social construct, yet they were the only source that improved detection of reflection (0.5862), while planning depended on the surrounding talk rather than on environment traces. Feature choice is a claim about the construct, not a budget decision (Zhang et al., 2026).
- **Behavioral traces are not measures of cognitive state — especially for special-needs learners.** Vasileiou et al. (2026) warn that interaction traces (time on task, repeated errors, Help-Seeking, irregular progress) can help teachers locate where a learner needs support, but are not transparent measures of internal states: slow responding may reflect careful thought, language processing, distraction, inaccessible design, or technical difficulty. “Algorithms should not infer an executive deficit or diagnostic status from behavioral data alone” — analytics are defensible as one source of information within professional assessment and dialogue with the learner.
- **Design analytics: mining planned activity sequences rather than traces (2026).** Divjak, Svetec and Horvat (2026) applied Markov chains and sequential pattern mining to the *designed* sequence of 29,064 teaching and learning activities across 554 courses planned in an open learning-design tool. The transition matrix peaked at Assessment to Discussion (0.332), self-transitions dominated

Practice (0.317) and Acquisition (0.292), and the strongest consecutive rule was Acquisition to Assessment to Practice to Practice (confidence 0.743, lift 1.449), while the most frequent four-step path was Acquisition, Practice, Practice, Assessment (120 occurrences). Discussion and Assessment were the most reachable types and Production the most distant and sporadic. The study is a reminder that learning analytics need not begin with LMS traces: design-time data can expose the pedagogical grammar of a course before any student arrives, though the authors stress that resemblance to flipped, inquiry-based or project-based designs is not evidence of intent.

- **Self-explaining distilled LLMs (2026):** A two-stage pipeline distills a black-box learning-analytics estimator and its post-hoc interpretation into a small, open-weight Large Language Models (LLMs) that returns both an individual-level estimate and a natural-language explanation. A faithfulness-first audit evaluates whether narrations match the attributions they describe; Simulation shows near-lossless recovery ($r > .90$) with an oracle mentor, offering a more transparent, deployable path for analytics (Distilling Black-Box Machine Learning into a Small, Self-Explaining Language Model for Learning Analytics).
- **Enablers of LA-based educational interventions (2026).** Svetec, Divjak & Kadoić (2026) identify and prioritize seven enablers of trustworthy LA-based educational interventions via Delphi + AHP + SNAP: institutional strategic orientation, pedagogical & other research foundations, available resources, pedagogical support, ethics & data governance, stakeholder engagement, and quality assurance. Institutional strategic orientation ranked highest (and most influential on other enablers), with available resources second. Trustworthiness (ethical compliance, transparent/unbiased algorithms, pedagogical validity) is framed as the prerequisite without which LA-based interventions are not meaningful.
- **LLM interaction depth predicts task quality but not recall (2026).** Tsiligkiris (2026) links turn-level LLM conversational telemetry (Depth/Volume/Pacing) to learning outcomes: explanation-seeking "depth" predicted independently marked task quality ($\beta = 6.27$) but not immediate recall — a dissociation between elaboration-driven comprehension and retrieval-driven consolidation that has implications for how Large Language Models (LLMs) interaction is measured and evaluated in LA.
- **A shared interaction unit is missing.** Across 46 categorizations from 33 studies there is no shared meta-characteristic — similar labels name different phenomena — so the review proposes the *interaction episode*, a goal-directed bounded exchange, as the unit for correlating dialogue with skill acquisition (Borchers, Jansen & Weidlich (2026)).
- **Simulating collaborative discourse for learning analytics.** Fang (2026) uses fine-tuned participant-specific LLM agents to reproduce collaborative problem solving dialogues, validated with Epistemic Network Analysis (ENA distance 0.17, permutation $p = 0.65$). The approach offers learning-analytics researchers a scalable way to generate authentic collaborative discourse for studying interaction dynamics, turn-taking, and thematic code trajectories without collecting new human data.
- **Open, reproducible data and trace-ready analytics.** ASTRA releases a synthetic Benchmark with a trace-ready schema (N=540; 360 sessions; 1,440 episodes) for analyzing interaction and participation balance in collaborative programming. Log and trace data are the natural

counterweight to self-report in this literature: the same construct is often measured twice, once by asking and once by observing, and the two do not always agree. Separately, an exploratory ML framework with SHAP analysis identified the learning-related constructs most associated with intended academic ChatGPT use among university students, prioritizing interpretability (An Exploratory Machine Learning Approach to Understanding Determinants of Future ChatGPT Use in Higher Education).

- **Reusable analytics infrastructure, validated only in-house (2026).** Bai et al. (2026) reproduced published findings from three Georgia Tech AI assistants by changing configuration values rather than code, though the claim rests on reanalysis of existing single-institution datasets and the one capability extension was done by insiders.

Connections

Learning analytics connects to Knowledge Tracing (the core analytic), Formative Assessment (analytics-driven assessment), Learner Modeling and Adaptive Instruction (the learner representation analytics populate), Privacy (the ethical constraint), and Edtech Platform (where analytics are deployed). Because prescriptive analytics are increasingly evaluated on simulated learners — where synthetic student cohorts substitute for real cohorts in controlled tests — learning analytics also connects to student simulation.

- **What dashboards make visible decides what teachers act on.** Köroğlu et al. (2026) reviewed 27 empirical studies (2016–2025) and built a socio-technical taxonomy of AI-supported lecturer decision-making across eight decision types: instructional, curriculum, assessment, feedback, learning-environment, emotional, administrative and ethical. Learning Analytics Dashboards were the most frequently reported system, and the coding shows support concentrated in the instructional, feedback and assessment decisions that behavioral text and log data can inform, while emotional, ethical, curriculum and learning-environment decisions were rarely supported. The authors read this as an attention effect rather than a capability limit: because the systems rendered behavioral student data visible and actionable, motivation, Metacognition, emotion and environment concerns fell outside what the data invited lecturers to consider.
- **Turning AI analyses into classroom talk is itself a teacher skill.** In four secondary mathematics lessons, one teacher's 47 whole-class orchestrations converted dashboard output into collective argumentation by selecting and sequencing students' warrants, and the study names four recurring types (Lee, Park and Lee (2026)).
- **Analytics that lightens a teacher's load is not analytics that lightens a learner's.** In a review of 23 studies of AI in embodied learning, 62.5% of 40 role tags were sensing roles that appraise a movement, trajectory or artifact — work that otherwise fell to a teacher — and the authors warn that a reduction in teacher workload should not be read as a reduction in learner load. Their reason is a limit on what this kind of coding can show at all: recording the function a system performs says nothing about its effect on the learner, so role frequencies cannot settle whether the system offloaded cognition or deepened it (Kim and Han (2026)).

Process-level instrumentation is the descriptive layer's next step down. Prol et al. (2026) extended an Open Source Parsons-problem platform to record every block placement, removal and submission as a chronological trace, pair each submission with per-block correctness coloring and an attempt history, and

optionally pass the traces through an Large Language Models (LLMs) pipeline that labels recurring difficulty patterns for instructor review. Across 68 students in an upper-division Java software-design course and 36 in an introductory Python course the analysis surfaced the same three difficulties — choosing the wrong exception type, substituting `return` for `throw`, and incorrect control-flow ordering — which correctness-and-attempt counts cannot expose, because they answer *whether* the arrangement was right rather than *what the process was*. The AI acts as an interpreter for the instructor rather than a scorer of the student, and its output is framed as a reviewable hypothesis about a class's difficulties rather than a grade.

- **The learning system wall: log data doesn't generalize across platforms.** MATHia, i-Ready, and IXL each define even basic constructs — an "attempt," a "hint" — differently, so models can't transfer between them. A work-in-progress response attacks the problem from the video side: a Gemini pipeline distills tutoring screen recordings into a single screenplay transcript aligned to native MATHia logs as ground truth. What video recovers that no single stream does: whiteboard Scaffolding, silent calculator work in external tools, and off-screen context that native logs reduce to "idleness." Open challenges remain in temporal anchoring, clock drift, and separating platform events from other learning processes. (Towards breaking the learning system wall using multimodal tutoring transcriptions)
- **Interaction logs can lose to a constant baseline.** Semester-level features from 16,851 LLM-tutor exchanges beat a median predictor of assignment scores by 0.114 points, an interval crossing zero, with 62.1% of error in the lowest quartile (Dong et al. (2026)).

Dashboards and early-alert systems concentrate the risk of Automation Bias: a flag asserts a judgment that a person may accept because it exists rather than because it was checked.

Common Misconceptions

- **"A knowledge-state estimate inherits its validity from the data." The Q-matrix linking items to attributes is an assumption, not data**: rejected entries for **14 of 918 analyzed items** means the mapping itself required adjudication. Validating the mapping is a step, not a formality.
- **LLMs reading clickstreams against named learning strategies.** Radmehr et al. (2026) stage an LLM pipeline that locates evidence for a strategy in a student's trace, judges adherence, and cites the actions behind the judgment, reaching overall quality of 0.735 in a harder simulation against 0.704 for a flat baseline.
- **"Analytics need clickstream traces."** Knowledge states can be estimated within Outcome-Based Education by **tracing course outcomes directly from LMS interaction and attainment data**, using OBE affinity mappings — the institutional record supplies the signal.
- **"Prediction without an action window is useful."** Progress prediction is most usable when it is **interpretable and paired with an action window**: Zhang, Jeffries and Koprinska (2025) predict module-level outcomes, which is a form an advisor can act on, unlike a raw score.

Platforms, openness and adoption

Technology Adoption Models

> **Technology Adoption Models** — the family of theories that explain and predict why individuals and institutions accept, adopt and keep using new technologies, of which the **Technology Acceptance Model (TAM)** is the most widely applied. In AI in education they are the standard lens for asking why learners, teachers and organizations adopt generative AI tools, and the knowledge base treats them together because GenAI-adoption studies draw on several members of the family rather than one.

Questions to Consider

- Think of a time you adopted a new app, tool, or AI service — and a time you abandoned one. What actually drove each decision: how useful it seemed, how easy it was, or what people around you were doing? Which factor do you suspect matters most, and can a survey really capture that?
- A common belief is that 'if a tool is clearly useful, people will use it.' Have you seen situations where a genuinely useful technology still failed to catch on, or a clearly limited one spread anyway? What might explain the gap between objective usefulness and actual adoption?
- Adoption frameworks like TAM were designed in the 1980s for fairly simple systems. If you've used generative AI, in what ways does it differ from a word processor or a learning management system — and why might a model built around 'ease of use' and 'usefulness' struggle to capture how people relate to something that talks back?
- Researchers often say perceived risk and trust matter less for AI adoption than expected. Before reading further, what do you predict: do students adopt AI because they trust it, despite risks, or are those concerns actually minor next to convenience and social pressure?
- The page argues that adoption frameworks treat using a tool as a one-time decision, but effective use may be an ongoing judgment. Where in your own or your students' practice does the line between 'choosing to use AI' and 'continually deciding how to use it well' seem to blur — and what would change if we measured that instead of mere uptake?
- Some researchers cluster learners into different 'adoption personas' instead of assuming one model fits everyone. What differences do you see among your own learners, colleagues, or students that a single average model of adoption might hide — and how could those differences shape how you support them?

Introduction

Meta-analytic evidence on AI adoption. A meta-analysis of tertiary students' AI adoption (233 correlations, 32 studies, N = 16,977) finds moderate positive correlations for individual (r = 0.57), contextual (r = 0.53), and technological (r = 0.50) factors, with usage intentions the strongest predictor (r = 0.64) and perceived risks/trust weaker than expected. Its central critique is that the field **over-relies on traditional TAM/UTAUT** frameworks that predate modern intelligent systems and neglect AI-specific factors such as anthropomorphism and ethics — arguing these gaps matter for advancing theory and evidence-based policy.

- Ease of use stopped predicting once the sample had already adopted. Wei, Zhang and Heo (2026) extend TAM on 526 design students with prior AIGC use and find perceived ease of use was the only technological perception not significantly associated with self-efficacy, while knowledge, trust, reliability, usefulness, intelligence and anxiety each were (Wei et al., 2026). Usage intention was strongly associated with reported dependence in cross-sectional data.

The model family

Technology Acceptance Model (TAM)

Proposed by Davis (1989), TAM explains adoption through two core beliefs — **Perceived Usefulness (PU)** and **Perceived Ease of Use (PEOU)** — which shape users' **Attitude (ATT)**, then **Behavioral Intention (BI)**, then actual usage. Grounded in information-systems theory (adapted from the Theory of Reasoned Action), TAM has become the dominant framework for GenAI adoption in education. In educational GenAI research it is frequently extended with AI Literacy, Trust, social influence, self-determination, and **critical use** to capture adoption complexity beyond simple uptake.

UTAUT / UTAUT2 / UTAUT3

The **Unified Theory of Acceptance and Use of Technology** consolidates TAM with eight prior models into four core determinants — performance expectancy, effort expectancy, social influence, and facilitating conditions (with UTAUT2 adding hedonic motivation, price value, and habit; UTAUT3 adding personal innovativeness). The knowledge base applies UTAUT across teacher and student populations: Austrian secondary math teachers (UTAUT with 448 teachers), pre-service science teachers in Ghana (UTAUT + TPB), and students in Lesotho (UTAUT3 + ARCS, using PLS-SEM and fsQCA). Jácome-Vásconez et al. extend UTAUT2 with explainable AI (Random Forest, SHAP, NCA, IPMA, K-Means) for 522 university students, finding **habit** the strongest predictor of ChatGPT intention and showing that **effort expectancy is a necessary condition rather than a linear driver** — a result only visible when XAI complements the regression.

In an already-adopted sample, habit carries the model and the expectancies go quiet. Pinedo et al. (2026) tested UTAUT2 on 310 marketing students at two Latin American universities: habit predicted intention at $\beta = 0.426$ and use at $\beta = 0.412$, and intention predicted use at 0.324. Performance expectancy (0.037), effort expectancy (0.054) and social influence (0.048) were not significant, in a model explaining $R^2 = 0.665$ of intention and 0.707 of use. The authors read the null paths as variance restriction in a population that had already adopted the tool; the outcome is self-reported use, not logged behavior.

Theory of Planned Behavior (TPB)

TPB explains intention through attitude, subjective norms, and perceived behavioral control. It is frequently paired with TAM/UTAUT in AI-adoption studies — e.g. Rizun et al. integrate TAM, TPB, UTAUT, and the FATE (Fairness, Accountability, Transparency, Ethics) framework to model the behavioral and ethical drivers of student ChatGPT adoption.

Adoption research usually stops at intention; a TPB extension that instead measured delay despite a genuine intention found perceived behavioral control the strongest negative predictor of GenAI-assisted learning procrastination (β = −0.331) across 1,243 undergraduates, with the intention–delay link significant only at moderate-to-high learning GenAI anxiety (Li et al. (2026)).

Diffusion of Innovation (DOI)

Rogers' DOI theory explains adoption as a social process in which innovations diffuse through populations over time, emphasizing innovation attributes (relative advantage, compatibility, complexity, trialability, observability) and adopter categories. It appears in the knowledge base's institutional-level analyses, e.g. Al-Rahmi et al. combine the Technology–Organization–Environment (TOE) framework with DOI to model organizational AI adoption in Saudi universities.

Technology–Organization–Environment (TOE)

TOE frames adoption as shaped by technological, organizational, and environmental contexts — a complement to individual-level TAM/UTAUT for studying institutional adoption (see Exploring Organisational Drivers and Innovation Attributes of Artificial Intelligence Adoption in Higher Education).

Applications in the knowledge base

Adoption models are applied across the knowledge base to model student and teacher uptake of AI tools:

- **Critical-use extension:** Nguyen et al. extended TAM with *critical use* for engineering/CS students, finding that attitudes and critical use directly predict intention — and that critical use safeguards against over-reliance.
- **Unified socio-cognitive model:** Asag & Al Mamun integrated TAM with UTAUT for engineering students in Bangladesh (explaining 64% of usage variance).
- **Person-centered profiles:** Rather than variable-centered models, Saihi & Ahmed cluster GenAI-adoption personas, and Chen et al. use latent profile analysis to identify four ChatGPT-acceptance profiles among pre-service teachers — showing the field's move beyond single-model, linear accounts.
- **Cross-cultural validation:** Martínez-Moreno et al. cross-culturally validate adoption-related motivation constructs across Switzerland and China.
- **A knowledge mediator beside the expectancy mediators:** Belief to behavior: how AI self-efficacy shapes AI acceptance through AI literacy place AI literacy between AI self-efficacy and acceptance in 622 undergraduates in Türkiye. The indirect path was significant (B = 0.15, 95% CI [0.12, 0.19]) and left a direct path intact (B = 0.43, R^2 = 0.29); acceptance also showed a weak negative association with AI anxiety (B = -0.34, R^2 = 0.05). Where the overtrust work below routes confidence through performance expectancy, this study routes it through what students know about the technology.
- **Psychological correlates:** Wu et al. build on TAM to relate motivation, Self-Efficacy, anxiety, and risk perception to acceptance of AI-assisted English learning.

- **Regulatory competence critique:** Kim argues that adoption-centered TAM models treat use as a stable decision, whereas effective AI use is an ongoing process of judgment, revision, and selective uptake — reframing AI Literacy as regulatory competence and Critical Thinking rather than acceptance.

Adding a TPACK-family capability alongside belief frameworks such as the Theory of Planned Behavior as parallel predictors invites construct overlap and leaves the causal ordering of capability, attitude and control undecided; the Capability–Decision Model instead places AI-TPACK capability upstream of attitude and perceived behavioral control (Mnguni (2026)).

- **ML determinants of ChatGPT adoption:** An exploratory ML approach examined how students' perceptions and demographics relate to intended academic ChatGPT use, using SHAP analysis to identify key learning-related constructs — prioritizing educational meaning over maximizing algorithmic performance (An Exploratory Machine Learning Approach to Understanding Determinants of Future ChatGPT Use in Higher Education).
- **Explainability and domain relevance as acceptance levers for teachers:** Adapting trust-in-automation theory to teacher acceptance of AI recommendations, Feldman-Maggor et al. (2025) found that understandability (raised by explainable AI) correlated positively with both trust and acceptance of an AI grouping tool, and that domain-driven explanations in curricular language outperformed data-driven feature-importance ones on all three. Acceptance was additionally driven by pedagogical alignment and workload-reduction potential — situational factors beyond trust that standard TAM/UTAUT constructs rarely capture, reinforcing the case for extending adoption models with context and explainability.
- **Acceptance measured at the level of instructional materials (2026).** Wang, Chuang and Wu (2026) operationalized Performance Expectancy, Effort Expectancy, Perceived Playfulness, and Behavioral Intention for two age-tiered AI literacy guidebooks used by 794 K-12 students and 37 teachers, validating the four-factor structure with split-sample EFA and CFA and supporting measurement invariance across the 9-12 and 13-18 editions. Younger learners reported higher levels on all four constructs, and playfulness was the strongest correlate of intention in both cohorts — with the standardized playfulness-to-intention coefficient exceeding 1.00 in the younger group and an HTMT of .950 between the two constructs. The authors read that as construct overlap and possible suppression rather than a giant effect, a useful reminder that acceptance instruments applied to materials can produce empirically entangled factors that complicate structural interpretation.

Limits and extensions

TAM's cognitive focus also under-captures emotional and relational dimensions of AI use. A qualitative study of nursing students and faculty found that, alongside the four classic TAM constructs, participants – mainly students – described AI as a source of psychosocial support: emotional comfort during stress and a confidential space for reflection. This extends perceived usefulness beyond performance gains to Well-Being in high-stress professional training, suggesting adoption models should attend to affective and psychosocial factors, not only instrumental utility.

Autonomy perception and risk aversion as tool-specific extensions. A mixed-methods survey of 287 GenAI-experienced teachers across 27 countries and regions (Dai et al. (2026)) extends TAM in a direction the model family has barely touched: the perceived *autonomy* of the tool itself. Adding perceived artificial autonomy (how independently teachers believe GenAI can carry out an assigned instructional task) and risk aversion to the classic constructs, their refined structural model explained 79.8% of the variance in behavioral intention ($\chi^2(97) = 202.597$, CFI =.963, TLI =.954, RMSEA =.062, SRMR =.041), with perceived usefulness again dominant (PU → BI β =.832, p <.001) and ease of use feeding usefulness (PEU → PU β =.479). The instructive results are the detours. Artificial autonomy did not act directly on intention (β =.026, ns) but acted through usefulness (AA → PU β =.188, p <.001; indirect AA → PU → BI =.156, 95% CI [.082,.240]) — teachers who saw GenAI as more capable found it more useful, not more immediately adoptable. Risk aversion lowered intention (RA → BI β = −.163, p <.001) without lowering perceived usefulness (RA → PU ns), because teachers' concerns centered on *students'* use — cheating and integrity, weakened foundational knowledge and higher-order thinking, hallucinations, reduced human interaction, and ethical, legal and equity risks — rather than on their own. Ease of use was non-significant overall (PEU → BI β =.068) but significant among the 225 teachers who had actually used AI in teaching (β =.138, p <.05), the familiar pattern that effort registers only after real encounter; attitude had to be dropped when its correlation with intention (r =.929) breached discriminant validity. Teachers placed GenAI at semi-autonomous levels (130 at Level 2, "teacher assistance"; 94 at Level 3, "partial automation"; one at Level 6) and insisted adoption decisions be made case by case. TAM still predicts intention well, but for teacher-facing AI the constructs that move the needle are tool-specific: how autonomous the tool seems, and whose use the risk attaches to. The authors' "frenemy" label — valued as a support tool, distrusted as an autonomous agent — is the teacher-side counterpart to the student-facing extensions catalogued above.

Risk perception as a dimension-specific extension. A survey of 814 Chinese university students (Du, Ning, Shi & Chen (2026)) folds Cognitive Appraisal Theory and Protection Motivation Theory into TAM/UTAUT2 to ask not whether students adopt generative AI but what they gain from it. The model family's assumption that risk uniformly suppresses adoption does not survive: risk perception splits into information, security, technical, ethical, and legal dimensions that move benefits in opposite directions. Security risk — a threat students believe they can manage through privacy practices — was *positively* associated with perceived academic assistance and skill development, consistent with problem-focused coping, whereas information risk, which learners cannot easily verify, eroded psychological and emotional support, daily-life, and leisure benefits through avoidance. Threshold analyses further showed effects that change sign beyond dimension-specific cut-points, and usage experience mattered independently: students with more than a year of GenAI use reported higher benefits across four domains. The practical implication for acceptance research is that "perceived risk" is too coarse a construct to model — controllability, not the mere presence of risk, is what determines whether students engage or withdraw.

A recent extension inverts the usual direction, placing subject-specific motivational beliefs upstream of the TAM perceptions rather than beside them. Xue, Xu, Qi & Lu (2026) report utility value predicting perceived usefulness at β = 0.43 and expectancy for success predicting ease of use at β = 0.39, while core TAM paths attenuate but stay significant.

Task–technology fit as a parallel path, and necessity as a separate question. Most extensions above add constructs *inside* the belief model. One sibling framework that TAM studies rarely carry is Task–Technology Fit, which asks whether a tool's capabilities match the demands of the specific task. Chu and Liu (2026)

joined the two in 405 design graduate students at Chinese universities, and fit acted as a second route into attitude rather than a determinant of usefulness.

Task characteristics fed fit at $\beta = 0.322$ and technology characteristics at $\beta = 0.266$. Fit then fed attitude at $\beta = 0.224$, beside perceived usefulness (0.376) and perceived ease of use (0.185), and attitude fed intention at $\beta = 0.388$. Self-efficacy carried the largest upstream coefficients, 0.458 on usefulness and 0.394 on ease of use. Perceived enjoyment raised ease of use (0.220) and left usefulness untouched (−0.033, $p = 0.483$) — an instrumental/affective split the classic model does not draw.

The methodological addition is the more transferable part. A multilayer-perceptron network reproduced the PLS-SEM importance ranking in all four models. Necessary condition analysis then found only two floors: self-efficacy for usefulness ($d = 0.125$, $p = 0.015$) and attitude for intention ($d = 0.132$, $p < 0.001$). Attitude at 22.1%, 34.3% and 46.4% of its scale was required for intention at 80%, 90% and 100%, so attitude behaves as a gate rather than a weight, which is a different claim from a path coefficient of 0.388. The caution sits in the outcome: $R^2 = 0.150$ and $Q^2 = 0.011$ for intention say the ten hypothesized paths leave most of the variance elsewhere.

Design features upstream of the beliefs, and importance that is not necessity. Zhang, Xin and Qing (2026) put six system features in front of the two TAM beliefs for 301 Chinese university students, borrowing a stimulus–organism–response frame. Personalization and interactivity moved perceived usefulness alone, while intelligence and content completeness moved ease of use alone. Responsiveness moved both; anthropomorphism moved neither. The model explained $R^2 = 0.244$ of intention (SRMR = 0.033), with ease of use ahead of usefulness on intention ($\beta = 0.340$ against 0.265). Ten-fold cross-validated network importance agreed, ranking ease of use at 100% against 84.70% for usefulness.

Necessary condition analysis then separated influence from requirement. Ease of use, the top-ranked predictor, failed outright ($d = 0$, $p = 0.592$). Usefulness was necessary but small ($d = 0.027$, $p = 0.011$). The authors read the split as a caution against treating a path coefficient as a floor. A strong coefficient says a unit of ease buys intention on average; only necessity says whether the other belief can be absent.

Risk's link to use also depends on the system: across the 49 TALIS 2024 systems that administered the items, perceived AI utility was positively associated with AI use in all 49, while perceived risk was negatively associated in 40 and positively in nine (Fang & Jin (2026)).

Performance expectancy can carry a relationship that acceptance research reads as intention to use. In Kim, Kim and Zhang (2026) performance expectancy predicted AI overtrust at $B = 0.6107$ and was the first mediator through which self-efficacy, intrinsic motivation and extrinsic motivation reached overtrust. The expectancy-only indirect path was positive for all three predictors, 0.1355 (95% CI [0.0542, 0.2330]) for self-efficacy, so expectancy was not merely predicting whether students would use the tool.

Common Misconceptions

- **"TAM's constructs explain adoption."** Asag and Al Mamun integrated TAM with UTAUT for engineering students in Bangladesh and explained **64% of** the variance. Substantial and incomplete at once: roughly a third of what drives adoption sits outside the classic acceptance constructs.

- **“Acceptance models need no domain modification.”** Adding **perceived artificial autonomy** — how independently teachers believe GenAI can carry out an assigned instructional task — and **risk aversion** to the classic constructs changed the model materially. The original constructs were built for tools without agency, and GenAI has perceived agency.
- **“A meta-analytic adoption estimate describes any population.”** The meta-analysis of tertiary students is the population-level estimate; the engineering result explaining 64% is a specific population. Importing one onto the other assumes a stability the evidence does not establish.

Open Education

> **Open education** — the movement and the practice of teaching with openly licensed content, and the pedagogy that treats students as producers of it rather than consumers. Its two artifacts are the open educational resource and the open pedagogical assignment; its license is what makes reuse lawful, and its claim is that both lower cost and widen authorship. Generative AI now presses on all three: it collapses the cost of making content, it muddies who authored a remixed resource, and it gives institutions a cheap alternative to the commons they were asked to fund.

Questions to Consider

- If a model can draft a course unit in minutes, what still justifies the license, the attribution trail, and the review process that open content carries with it?
- A resource can be open by license and closed in practice: the file is downloadable but the course around it assumes a lab, a language, or a connection students do not have. Which openness are you measuring when you report adoption?
- Open pedagogy asks students to publish their work. Who owns what a student makes with a generative tool, who consents to its release, and who carries the cost when it is wrong?
- Teacher AI literacy predicts open teaching practice, but the relationship weakens as institutional support rises. What does that inversion imply about training programs built on the assumption that support only helps?
- If AI-generated text is not copyrightable, is a machine-written textbook automatically open, and what does that do to the case for public funding of OER?

Introduction

Open education is not open source, and the confusion costs both. Open source is about **artifacts a developer ships and licenses**, principally code, model weights and datasets, so that a system can be licensed, audited, modified and redeployed. Open education is about **what a teacher assigns and what a student produces**, and its licensing exists to let a second institution substitute, translate, remix or correct a resource without asking permission. The two share a legal machinery (Creative Commons, in education; permissive software licenses, in code), a production model (volunteer and grant-funded communities), and now a shared antagonist in generative AI, whose capacity to produce the artifact nearly free unsettles the economic case for both.

They differ where it matters. An open-source release is judged by whether the system can be rebuilt and inspected. An open resource is judged by whether a teacher with different students, a different language and a different budget can actually use it, which is a pedagogical claim rather than a technical one, and which is why open education has always carried a practice argument alongside its licensing argument. Deimann and Lukács (2026) make the sharpest version of that point: after twenty-five years of openness advocacy, the institutional regime in the middle of education was left intact, because the movement concentrated on declarations and niche projects.

The AI-era literature in this knowledge base is therefore about three things at once: the resource, the practice, and whether either survives when generation is nearly free. On the resource, the questions are who makes it, who licenses it, and whether an AI-written one counts. On the practice, they are what open pedagogy asks of students and whether it teaches them anything measurable.

What openness actually covers

An open educational resource is content released under a license that permits reuse, revision, remixing and redistribution. Everything else in the field is downstream of that permission and of the obligation to attribute it. González Miy (2026) shows what the obligation looks like in a small project: eleven participants working online for two weeks produced a six-page site, a chatbot, a manual and five video tutorials, released under CC BY-NC-SA, and the resulting package scored high on transparency while scoring only medium on licensing, replicability, adaptability and accessibility. Open in name, partially open in use.

The licensing literature is granular because the failures are granular. Ryu (2026) builds a seven-principle rubric for reviewing openly licensed AI literacy material from a purposive corpus of sixteen core papers, a seventeen-paper extension and thirty-six targeted references. Atenas, Farrow, Caldwell, Costello and Havemann (2026) argue that the unit of governance should move from the resource to the infrastructure that hosts it, since a commons of individual files without a maintained platform is a fragmentation problem rather than a commons.

Generation collapse and the digital public goods turn

Course production is where the shift is already measurable: MAIC reports collapsing MOOC production from roughly $25,000 and 60 hours per course to under $2 and 30 minutes with Large Language Models (LLMs)-driven multi-agent generation. If production cost approaches zero, the argument that OER saves money loses its force, and what remains is licensing freedom, verifiability and quality assurance.

Tlili, Farrow, Bozkurt, Amiel, Wiley and Downes (2026) organize that shift around five framing questions and reach an unsettling legal reading. Because the United States Copyright Office treats prompts alone as insufficient for authorship, a purely AI-generated resource may fall into the public domain and qualify, on a strict reading, as open by default. Their term for the opposite failure is openwashing, where an artifact is presented as open while its training data, its pipeline or its license is not. The authorship question is also a legal question before it is a licensing one, and the legal and copyright side runs through misconduct as much as through ownership.

The policy response in this literature is to reclassify. Atenas and colleagues propose treating OER as digital public goods, which moves the remedy from producing more content to building publicly governed, non-commercial infrastructure. They measure that infrastructure against the ROAM-X principles and the FAIR data standards, and describe a landscape already holding over two billion openly licensed works and 303 Internet Universality Indicators. That is a defensible redirection of a movement that spent two decades on content production.

The institutional case for openness is also made on autonomy. Panda (2026) argues in an editorial that digital transformation in open and flexible learning is pedagogic transformation rather than technology adoption, and that a technology earns credence only when it aligns with an appropriate pedagogy in a local context.

Rodés-Paragarino and Atenas (2026) turn that into a seven-pillar framework for responsible integration of OER and generative AI, built from a documentary analysis plus expert validation and a participatory workshop with 81 participants in Bilbao in December 2025.

Open pedagogy and the practice turn

Open pedagogy moves the student from consumer to contributor: an assignment produces something that is published, licensed and reusable. Clinton-Lisell (2026) provides the field's cleanest test of the idea. Two sections of an introductory child development course updated the same textbook, one of them with generative AI tools. Across 113 assignments, students in both sections reported growing information literacy skill, and the gain was statistically indistinguishable between them: a time effect of $F(1, 84) = 47.30$, $p < 0.001$, partial $\eta 2 = 0.36$, against a time by section interaction of $F(1, 84) = 0.04$, $p = 0.85$. The AI section completed more work and scored slightly lower, 174.73 against 173.86 out of 180.

Practice has a maturity literature of its own. Duan (2026) screened 540 records to fourteen models of open educational practice under PRISMA 2020, compared them on three dimensions, and concluded that generative AI sits underneath established models rather than displacing them, an argument the paper locates against Technological Pedagogical Content Knowledge (TPACK). Ahmadfard (2026) reaches a similar conclusion about interactivity in a structured review running from 1970: interactive features are a design argument more than a demonstrated effect, and the strongest effect sizes it reports are borrowed from earlier physics education work rather than measured in OER.

Two further studies show how quickly the practice layer becomes a governance layer. Patiño, Martínez-Pérez, Ramírez-Montoya and Miranda (2026) document a UNESCO and ICDE residency of 110 participants from 13 countries in 10 teams, but their survey base is 72 responses from 54 institutions with no response rate, which is thin support for a roadmap aimed at the UN 2030 Agenda. And Guo, Lu and Gao (2026) surveyed 512 teachers across 30 Chinese provinces on whether AI literacy translates into open teaching practice, finding an indirect path through innovative behavior of 0.218 at low institutional support that falls to a non-significant 0.042 at high support.

Equity, sustainability and the Global South

The equity argument for open content is the oldest one: a resource without a price cannot be priced out. It is also the one most easily asserted and least often tested. The AI-era versions are more careful. Atenas and colleagues frame OER as a lever for marginalized communities and for meaningful participation in data collection, while warning that over-reliance on generated resources risks devaluing human Creativity and judgment. Tlili and colleagues name the mechanisms by which generation degrades that lever: translation error, training-data bias, and a hallucination loop in which generated content is recycled into the corpora that train the next model.

Sustainability enters twice, as funding and as energy. The digital public goods argument is essentially a sustainability argument: a fragmented commons of grant-funded files does not outlive its grants, whereas publicly governed infrastructure might. The environmental case appears in the wider openness literature and in this knowledge base's Sustainability concept, where the reporting of model inference cost is treated as an obligation of open practice rather than an afterthought.

The Global South dimension is where the evidence thins most. The batch's non-Western cases are real but few: a Latin American cooperation residency, Chinese open-university teachers, and a framing of infrastructure as the precondition for participation. Claims that openness automatically redistributes capacity are not supported by these studies, and several of them say so.

Where writing and recommendation systems meet the argument

Two papers in this batch are about production systems rather than policy. Peng (2026) develops a hybrid deep recommender for OER and reports 93.6 percent accuracy, 92.5 percent precision, 91.0 percent recall and a 90.2 F1 score on 2,400 interaction records. Its own comparison table shows a BERT4Rec baseline at 90.8 F1 with equal recall, and the dataset section leaves user count, item count and sparsity as placeholders. The modeling claim is modest; the pattern is familiar, in that an advance over a strong baseline is smaller than the headline.

The second is a reminder that a generative system can be open and its content closed. OATutor pairs an MIT codebase with CC BY OpenStax algebra texts, which means the licenses of code and content have to be kept compatible by design. That single technical obligation is the clearest practical form of the open source and open education relationship: different objects, same legal machinery, and a compatibility constraint that falls on whoever assembles both.

Common Misconceptions

"Open education and open source are the same openness." They share licensing machinery and a production model and they are not interchangeable. Open source is a claim about a buildable, inspectable system; open education is a claim about a usable, adaptable teaching resource. A school can run entirely open-source software over a closed textbook, and many do.

"Open means free to the student, which is the whole benefit." Cost is the measurable half. The other half is permission: a resource that may be revised is one a second institution can fix, translate and localize. Studies in this batch report completion and satisfaction far more often than adaptation, which is why the adaptation claim remains largely untested.

"AI makes content so cheap that OER is obsolete." The opposite reading is available and better supported. If generation is nearly free, the scarce goods become the license, the attribution trail, the review process and the maintained platform. That is why this literature converges on governance and infrastructure rather than on production.

"Adding AI tools to an open assignment improves the learning." The one quasi-experimental test here found perceived skill growth in both arms with no detectable difference between them, alongside higher completion and marginally lower scores in the AI section. AI changed what students produced and did not change what they reported learning.

Open Source

> **Open Source** — the use of openly licensed *models, code, data, and content* in AI in education. Openness is the knowledge base's main counterweight to vendor lock-in and data exposure: open-weight models can run on campus hardware to satisfy FERPA, GDPR, and EU AI Act obligations, openly licensed corpora can be indexed and fine-tuned without publisher permission, and open benchmark and dataset releases make research replicable. The burdens are equally real: infrastructure and safety assurance, maintenance that outlives the grant, and quality that openness does not by itself guarantee.

Questions to Consider

- "Open source" is often heard as "free and easy." Which of the four layers below — models, code, data, or content — actually costs your institution the most to adopt, and why?
- Open weights make local deployment possible, but someone still has to host, patch, and evaluate the system. Who should own that work after the initial project ends, and who pays for it?
- One study here found a 32B open model outscoring a far larger proprietary system on pedagogical knowledge, while another found every open model tested below the human baseline on scientific-visualization literacy. How do you decide which benchmark is the right one for your decision?
- A single openly licensed corpus is what lets a school run an on-premise assistant over its own course materials. What obligations come with that — to the original authors, to students whose data is indexed, and to the license itself?
- If generative AI can produce a course in under half an hour for a couple of dollars, what is the remaining rationale for open educational resources — cost, licensing freedom, quality assurance, or something else?
- Should institutions treat open-source adoption as a procurement decision, an infrastructure decision, or a pedagogical one? What breaks if it is treated as only one of them?

Introduction

Loosely, "open" in AI education means that four kinds of artifact are available for inspection, reuse, and modification: **model weights**, **source code**, **data and evaluation instruments**, and **educational content**. The knowledge base's articles cluster unevenly across these layers, and the resulting picture is more useful than the slogan: openness buys specific things — local control, auditability, replicability, and legal clarity — and it costs specific things — infrastructure, expertise, maintenance, and a quality-assurance burden that moves from the vendor to the institution.

Open models and open weights

Open weights matter most where student data cannot leave campus. LaTA is a drop-in, FERPA-compliant local-Large Language Models (LLMs) autograder for upper-division STEM coursework built on instructor-

authored rubrics and reference solutions, with zero marginal cost per submission. SCRIPT, a Python tutoring system at Bielefeld University, deliberately **avoids commercial LLM APIs** and self-hosts an open-weight Llama-70B model to meet the GDPR and the EU AI Act (which classifies some AI-in-education uses as high risk), separating IP logs from the tutoring system, using pseudonymous usernames, and recording keystrokes only with explicit consent — a choice the authors also credit with lower environmental impact and better reproducibility.

Quality is no longer the automatic price of openness. EduQwen applies reinforcement learning (DAPO) and supervised fine-tuning to an open model family, mining 440 hard negatives, generating 40,000 synthetic responses down-selected to 1,050 difficulty-ordered examples, and reaching **96.52%** on the pedagogy benchmark — above Gemini-3 Pro's 90.55% — at 32B dense parameters. AiAWE reaches similar conclusions for automated writing evaluation: a LoRA-adapted open-weight Gemma-3-27B-it outperforms LLaMA-3.3-70B and a fine-tuned GPT-3.5 baseline on 480 TOEFL essays and runs on a consumer-grade server, with the striking subsidiary finding that parameter count is *not* a reliable predictor of downstream performance under LoRA adaptation. The counter-evidence deserves equal billing: a benchmark of six MLLMs (three closed, three open) found every open-source model below the human baseline on scientific Visualization literacy while Gemini exceeded the human mean on several subsets. Openness raises the ceiling on control, not on capability.

OmniEdu releases the whole pipeline rather than just weights: capability-balanced supervision over a 69,999-example mixture lifted every scale of an open 4B/9B/27B K–12 family — the tuned 4B model gained 55 points of MathTutorBench scaffold win rate over its base — while knowledge-state diagnosis stayed its weakest capability at 54.04% (Liang et al., 2026).

Open tools, tutors, and research infrastructure

The clearest case for open code is replication. OATutor — the first fully open adaptive tutoring system built on ITS principles — pairs an **MIT-licensed codebase** with a **Creative Commons (CC BY) content library** from OpenStax algebra textbooks, plus knowledge tracing, A/B testing, and LTI support; its explicit design goal is that a researcher can run an experiment and then publish the entire end-to-end framework, content, and platform as a repository link. StanBKT makes the same argument at the method layer, replacing expectation-maximization point estimates with full Bayesian inference (HMC, variational inference, Pathfinder, optimization) in an open Python package that exposes the uncertainty A/B comparisons of adaptive interventions depend on. Deeptutor releases a complete agentic tutoring framework with a trace-forest learner memory — Apache 2.0, and by late 2026 a full learning workspace rather than only the pipelines its paper benchmarks — and MAIC's classroom generator OpenMAIC ships under MIT alongside the study that evaluates it, so a course can be generated, self-hosted and inspected rather than only read about; VISMATIC publishes its containerized sandbox for process-oriented monitoring, so other institutions can adopt the integrity model rather than the vendor's version of it. Open code also carries the transparency burden: the scripts for MathBuddy's affect-aware tutoring prompts are published for inspection and further pedagogical training work. Open infrastructure sets the reference point for what educational agents should do: the knowledge base's scoping review of 474 agentic-AI studies uses a fast-growing open-source agent project as its "frontier agent paradigm" benchmark and finds educational systems still lacking governed tool orchestration, persistent memory, long-horizon planning, and auditable action.

Open benchmarks, datasets, and method transparency

Several contributions here are open *evaluation infrastructure* rather than systems. The Pedagogy Benchmark (CDPK + SEND, built from genuine Chilean teacher-exam items) spans 97 models: open-weight DeepSeek R1 reached 86.65% against a top-10 of mostly closed reasoning models, and the cost–accuracy frontier moved from ~50% to ~82% at $0.10/M input tokens between April 2024 and June 2025. Open Qwen-3 8B at 3.5¢ nearly matched the best April-2024 closed model at over 400× lower cost. Performance drops sharply below roughly 8B parameters, which is a practical sizing constraint for campus deployments. ASTRA releases a dataset, schema, and prototype for trace-based evaluation of socially intelligent multi-agent tutoring (540 participants, 360 sessions, 1,440 task episodes). IKS-Instruct shows the cultural case for open data: 24,795 instruction–response pairs across seven languages and 41 pedagogical techniques drawn from Vedic and classical sources, aligned to the CBSE curriculum, which let a compact 7B model approach a much larger general-purpose reference model (median judge score 6.39 vs 6.54) at a fraction of the deployment cost. Student-authored benchmarks are another route to openness: AcademiClaw curates 80 long-horizon academic tasks from 230 student-submitted candidates (spanning 25+ professional domains, 16 requiring CUDA GPUs, run in isolated Docker sandboxes) and extends an open agent ecosystem into academic-level evaluation. Eimler et al. (2026) argue that openness is an environmental obligation as well: reviewing all AIED 2025 papers, they found an “LLM adoption without disclosure” pattern and responded with an open-source measurement methodology — software tools plus a formula that estimates computational expense even when parameter counts are unknown.

Where open content meets open code

Open educational resources have their own page, Open Education, because the argument there is pedagogical and licensing-led rather than infrastructural. What belongs on this page is the seam where the two openesses meet, and it is narrower than it looks.

The seam is a license-compatibility constraint. OATutor pairs an MIT-licensed codebase with a CC BY content library of OpenStax algebra textbooks, which means the terms of the code and the terms of the content have to be kept compatible by design, and a permissive license on one does not supply the other. The seam also appears when an openly licensed corpus is what makes an on-premise system lawful to run: Shen et al. (2026) index 82 OER documents into a knowledge-base assistant on a 12 GB consumer GPU, and the whole story is an open-source story about quantization, hallucination and provenance rather than an argument about textbooks.

What this page does not do is argue for the resource. Whether a machine-written textbook is open by default, whether a license survives a generated remix, and whether open pedagogy teaches anything measurable are questions for Open Education, and they are the questions the field’s current literature is actually about.

Benefits and burdens

- **Benefits.** Data sovereignty and regulatory compliance (Privacy, AI Regulation in Education) through local hosting; cost control, since local inference has no per-query fee and open models approach proprietary quality at a fraction of the price (Application-Driven Pedagogical Knowledge Optimization of Open-Source LLMs via Reinforcement Learning and Supervised

Fine-Tuning); reproducibility, because the framework, prompts, content, and data can ship with the paper (OATutor: An open-source adaptive tutoring system and curated content library for learning sciences research, ASTRA: A synthetic benchmark for trace-based evaluation of socially intelligent multi-agent tutoring and participation-balanced collaboration in introductory programming); auditability and safety review under institutional governance; and the ability to fine-tune for a specific Pedagogies and Teaching Strategies or a specific community's knowledge base (IKS-Instruct: A 24,000-Example Multilingual Dataset for Teaching Language Models Indian Knowledge Systems).

- **Burdens.** Local hosting requires hardware and expertise many institutions do not have; quality and safety are not guaranteed out of the box — open models may trail human baselines on specific literacies (Benchmarking Multimodal Large Language Models for Scientific Visualization Literacy) and quantization raises hallucination rates unless mitigated (Towards sustainable AI knowledge-base assistants in computer science education: on-premise deployment and optimization with open educational resources); someone must maintain the system after publication (Programming Intelligent Tutoring Systems documents a small PhD-student team, work-in-progress security exposure, and a substantial compliance burden); and an open license is a permission, not a working product — the maintenance that keeps a released system usable falls to whichever Educational Technology Developers built it, and their funding and incentives decide whether a forkable repository, a maintained product, or neither is what an institution inherits when the grant ends.

Putting openness into practice

- **For instructors and institutions:** check the license of the *content* as well as the code before adopting a system — MIT code over CC BY textbooks is reusable, but a permissive license does not guarantee that tutoring pathways, item banks, or translations exist. Prefer open models when student data legally cannot leave campus (LaTA: A drop-in, FERPA-compliant local-LLM autograder for upper-division STEM coursework, Programming Intelligent Tutoring Systems), but benchmark the model on *your* task rather than trusting general leaderboards (Benchmarking the pedagogical knowledge of large language models). Budget for someone to run and evaluate the system after the pilot.
- **For developers and researchers:** ship the whole thing — OATutor's end-to-end release (code, content, experiment harness) is the replicability standard this literature keeps rewarding. Release prompts and extraction schemas alongside weights (Programming Intelligent Tutoring Systems, MathBuddy: Affective Math Tutoring). Report compute and carbon (The Environmental Cost of LLMs in AIED: Reporting and Practices). Ground assistants in openly licensed corpora so provenance is checkable and adaptation is lawful (Towards sustainable AI knowledge-base assistants in computer science education: on-premise deployment and optimization with open educational resources). Use quantization-aware fine-tuning rather than plain quantization if accuracy and energy both matter, and keep code and content licenses compatible.

Common Misconceptions

“Open weights, open source, open content and open pedagogy are the same openness.” They are four different things and they fail independently. The resource and practice arguments live on Open Education; this page covers the artifacts a builder ships and licenses. Open *weights* permit local deployment; open *source* permits modification; open *content* permits reuse and adaptation; open *pedagogy* concerns who decides what is taught. A model with open weights and a proprietary training pipeline, wrapped in a tool with a closed interface and an all-rights-reserved content library, is “open” in one of the four senses and closed in three.

The word itself is contested upstream. Deimann and Lukács (2026) observe that the openness debate reached AI through the open-source community, with the first Open Source AI Definition published in 2024, and they argue that openness functions there as an imaginary rather than a property: an aspiration that institutions adopt in language while the surrounding regime stays intact. That is a useful check on this page, because a license is a property and a movement is not.

“Open means cheaper.” Open weights make local deployment possible, but **someone still has to host, patch and evaluate the system** — and that someone needs to outlive the grant that funded the work. The burdens named in this literature are concrete: infrastructure, safety assurance, and maintenance. Total cost can exceed a license fee, and institutions that treat openness as a saving frequently discover the maintenance obligation after the project staff have dispersed.

“Closed frontier models are simply better, so open alternatives are a fallback.” The gap is narrower than that assumption implies. In the Pedagogy Benchmark (CDPK + SEND, built from genuine Chilean teacher-exam items) spanning 97 models, open-weight **DeepSeek R1 reached 86.65%**, against a top-10 made up mostly of closed reasoning models — and the cost–accuracy comparison runs further in the open direction. The remaining argument for openness is therefore about control and auditability, not about a capability sacrifice.

“Releasing the weights is releasing the work.” The stronger open contributions release the pipeline. OmniEdu publishes capability-balanced supervision over a 69,999-example mixture rather than final weights alone, lifting every scale of an open 4B/9B/27B K–12 family, with the tuned 4B model gaining **55 points** of MathTutorBench Scaffolding performance; EduQwen likewise documents its RL and fine-tuning procedure, including 440 mined hard negatives and 40,000 generated responses. Weights without the recipe reproduce an outcome without reproducing the method.

- How Can We Make AI Better at Supporting Learning in Our Own Subject?

Edtech Platform

> **Edtech Platform** — the digital systems, learning management systems (LMS), tutoring systems, and online learning environments through which AI is delivered to learners and educators. In AI in education, the platform is the *infrastructure layer* that determines whether an AI capability reaches students, how it is deployed (open vs. proprietary, integrated vs. standalone), and who can access, adapt, and evaluate it. Research in this knowledge base examines platforms from multiple angles: their design, their take-up and engagement constraints, their institutional governance, and their equity implications.(Access is Not Enough: Human Support Improves Engagement with AI Tutoring) (OATutor: An open-source adaptive tutoring system and curated content library for learning sciences research)

Questions to Consider

- Think of the last AI tutoring or feedback tool you encountered. Now think about where it actually 'lived' — the LMS, platform, or app that packaged it. Does that container feel like a neutral delivery vehicle, or could its design choices (open vs. proprietary, integrated vs. standalone, cloud vs. local) have changed what you could do with it?
- One study found that nearly half of students never used a well-designed AI tutoring platform, and heavy users skewed toward higher-achieving students. If a tool is effective 'in principle' but students don't use it, is the capability or the platform the real problem? What would that mean for how you evaluate edtech?
- Proprietary AI platforms can confine researchers to a handful of closed systems, while open platforms like OATutor let anyone fork, experiment, and publish. What might be lost — for research, equity, and institutional autonomy — when AI education is delivered through closed, opaque platforms?
- How much does a platform's business model — who pays, who owns the data, what gets optimized — shape the learning that actually happens on it? Where would you look to see that influence?
- Some new 'AI-native' platforms replace the one-video-for-many-students MOOC model with a multi-agent classroom built around each learner. Before reading on, what would you worry about losing when instruction becomes one-to-one with agents instead of one-to-many with instructors?

Introduction

The platform sits between an AI model or capability and the learner. It is the container that packages tutoring, assessment, feedback, and administration into something usable — and, critically, it shapes learning outcomes through its design choices, its accessibility, and its underlying business model. The concept spans learning management systems like Moodle, large-scale online platforms like MOOCs, dedicated intelligent tutoring systems, and emerging agentic or AI-native course platforms. Naming the container is not the same as naming its authors: the platform is the deployed system, while the stakeholder that decides what it does is

Educational Technology Developers — which matters here because the take-up, equity-skew and procurement findings below are usually consequences of design choices made before a platform ever reached a classroom.

What a platform does in AI in education

Platforms in AI in education perform several distinct functions:

- **Deliver instruction and tutoring** — the container for AI Tutoring and Intelligent Tutoring systems, from LMS-embedded tutors to standalone adaptive tutoring platforms.
- **Manage the learning environment** — course organization, enrollment, progress tracking, and administration that traditional LMS platforms provide.
- **Host assessment and feedback** — where Automated Assessment, Formative Assessment, and feedback loops run.
- **Collect and analyze learning data** — the substrate for Learning Analytics and Learner Modeling and Adaptive Instruction.
- **Govern access and deployment** — decisions about Open Source vs. proprietary, local vs. cloud, and which institutions and learners can use it.

Key findings from the knowledge base's articles

Take-up, not capability, is often the binding constraint

A platform can be effective in principle yet fail in practice if learners do not use it. Two RCTs of an AI literacy (reading) tutoring platform found that **nearly half of control students never used the platform** and users averaged only 2–5 minutes per week — far below the dosage needed for reading gains. An in-person engagement tutor raised usage and engagement substantially but still did not produce achievement gains, and platform users skewed toward higher-achieving students, raising equity concerns.(Access is Not Enough: Human Support Improves Engagement with AI Tutoring)

Sequencing matters as much as capability: a review of 100+ AI-in-education studies (2020–2025) places end-to-end platforms at the top of an adoption stack, arguing institutions should settle formative assessment, leadership capacity, and shared norms before buying the platforms that scale them (Raza & Farooq (2025)).

The gap is message-level, not logins: in a two-year cluster RCT, 96% of students tried Khanmigo but the median student messaged it in only 17% of sessions where they made a mistake, and ~14.5% of messages carried a genuine mathematical question or reasoning step — at $15 per student per year (Oreopoulos and Low, 2026).

The binding constraint is where the AI sits inside the platform: in a 6,000-student middle-school trial, the measured effect came from structured touchpoints inside the practice environment — 2.0 "help me get started" uses, 2.3 post-mistake walkthroughs and 3.2 step explanations per mastery student — while AI access alone added little (Oreopoulos et al. (2026)).

Which tools educators report using, and what gates access

A rare census of educator-reported platform choice comes from a 2026 typology built from 211 educators across nine countries. The tools that reach classrooms are disproportionately the ones with a free tier, because a publicly available free version was an inclusion criterion, and the most-nominated entries are general-purpose assistants and media generators rather than purpose-built platforms. Roughly half of the fifty tools listed produce images, audio, video or slide decks, while document-grounded assistants (NotebookLM, Elicit, SciSpace, Humata, Research Rabbit) form the most coherent cluster in the research category. Dedicated tutoring systems appear as a small, subject-specific group rather than the center of reported use — which frames the take-up problem above in a wider setting, where a platform competes for attention against general-purpose tools that students and instructors already have open.(Typology of Generative AI Tools for Education)

The platform model matters: open vs. proprietary

- **Proprietary platforms** create barriers to research: researchers who want to replicate or extend Adaptive Learning experiments are often confined to a small number of closed platforms.
- **Open platforms** lower this barrier. **OATutor** is the first open-source adaptive tutoring system built on ITS principles — an MIT-licensed codebase with a Creative Commons algebra content library, Knowledge Tracing mastery estimation, and built-in A/B testing — letting researchers fork, experiment, and publish the full end-to-end system.(OATutor: An open-source adaptive tutoring system and curated content library for learning sciences research)
- **Transparency is front-loaded.** In the same audit of 48 platform policies, data collection and third-party sharing were disclosed comparatively well while AI-specific disclosure and accountability lagged, and 16 of 48 platforms (33%) made no meaningful AI disclosure despite visible AI features (Nair & Greenstadt, 2026).
- **The LMS API bounds what a game-integrated platform can assess.** A hypergamification pilot that generated a playable world from Blackboard content could not render multiple-choice or open-ended questions, because student-scoped tokens returned no question content and no endpoint existed for posting runtime answers (Yusubov et al., 2026).
- **Isolation and cost are platform design variables.** VISMATIC pairs rootless containers — which, unlike JupyterHub, prevent lateral movement and host compromise — with API-level process telemetry, running 19 students and 1,880 logged events on a single Raspberry Pi 5 node rated for 10 to 20 (Arroyo et al. (2026)).

AI-native platforms are reshaping online education

The platform paradigm itself is evolving. **MAIC** (Massive AI-empowered Course) replaces the MOOC's "one video for N students" model with an Large Language Models (LLMs)-driven multi-agent classroom — "N agents for 1 student" — using specialized Teacher, Assistant, Classmate, and Analyzer agents to deliver personalized, adaptive learning at scale. It reduces course production from ~$25K/60 hours to under $2/30 minutes.(From MOOC to MAIC: Reshaping Online Teaching and Learning through LLM-driven Agents) Similarly, AI-integrated LMS designs propose moving beyond workflow-only platforms toward real-time

instructional support with policy-gated (bounded) AI, formative hinting, spaced review, and teacher dashboards.(AI-Integrated Learning Management System for Middle School: A Longitudinal Study of Learning Outcomes Through High School and Beyond) At the other end of the deployment spectrum, classroom-embedded AI must prove feasible in live physical environments. The Community Builder (CoBi) — a classroom-wide platform that uses speech recognition and language understanding to visualize small-group collaborative discourse — was successfully deployed across noisy middle-school classrooms using commodity microphones and a scalable cloud pipeline, showing that real-time speech-AI infrastructure can function in authentic K-12 settings even as interface mismatches (teacher vs. student views of whether feedback was group- or class-level) created deployment friction.

Interest-based and context-aware platform features

Platforms can personalize beyond performance data. **Taklif.AI** is an LLM-powered platform that generates college assignments based on students' **extracurricular interests and cultural contexts**, aligning with Culturally Relevant Pedagogy and shifting from one-size-fits-all assignments toward interest-driven engagement.(Taklif.AI: LLM-powered platform for interest-based personalized college assignments)

Purpose-built layers over general models

The platform's contribution is often the structure a general model lacks. LearnMate^2 wraps an LLM in study planning, in-context help and performance-responsive activities, and in a 16-participant comparison it beat Khan Academy paired with Gemini 2.5 Pro on both quizzes (M = 13.375 vs 10.875, p = .0126; 7.875 vs 5.875, p = .0012). EduSim-LLM translates natural-language instructions into CoppeliaSim robot behavior for beginners, succeeding on 100% of simple tasks but 88.9% of complex ones across 108 cases.

Implications for design and research

1. **Design for take-up, not just capability.** A platform's effectiveness depends on whether learners actually engage with it; support structures, onboarding, and scheduling matter as much as the AI itself.(Access is Not Enough: Human Support Improves Engagement with AI Tutoring)
2. **Treat platform structure as an equity lever.** Who benefits from a platform depends on access, infrastructure, and engagement constraints — platform design must be examined through an Equity lens.(Access is Not Enough: Human Support Improves Engagement with AI Tutoring)
3. **Prefer open, replicable platforms for research.** Open-source platforms like OATutor enable reproducible adaptive-learning research and a shared evidence base.(OATutor: An open-source adaptive tutoring system and curated content library for learning sciences research)
4. **Design AI-native platforms with governance and bounds.** Privacy-first architecture, data minimization, auditable logs, and role-based access are critical as platforms become AI-integrated — connecting to Privacy and AI Governance concerns.(AI-Integrated Learning Management System for Middle School: A Longitudinal Study of Learning Outcomes Through High School and Beyond) Privacy can be built into the pipeline rather than the policy: a classroom incident detector trained on anonymized pose trajectories keeps facial and appearance cues for minors out of the system, though every method lost accuracy in zero-shot transfer to real classrooms, where the proposed model's best accuracy was 63.41% (Parmar et al. (2026)).

5. **Explain recommendations in the teacher's domain language.** A platform's AI features earn trust and uptake when their explanations are understandable and pedagogically meaningful: in a within-subject experiment with an AI grouping-recommendation tool (GrouPer), Feldman-Maggor et al. (2025) found domain-driven explanations framed in curricular language increased teachers' understandability, trust, and acceptance significantly more than raw feature-importance explanations — and that real classroom use still mattered for full acceptance.(The Impact of Explainable AI on Teachers' Trust and Acceptance of AI EdTech Recommendations: The Power of Domain-specific Explanations)
6. **Separate the system that produces evidence from the one that grades it.** When agents can complete a course on a learner's behalf, Srivastava (2026) argues a platform must emit contemporaneous, inspectable evidence of the learner's reasoning and must not be its sole grader — the environment, issuer and verifier should be independent.(Credentials That Carry Their Evidence: Credential design, dynamic tiering, and approved use when AI agents can do the work)
7. **Generate representations at design time, not at runtime.** Neshaei et al. (2026) argue runtime adaptation cannot be verified at scale and propose encoding content as modality-agnostic semantic cards, from which interactive, audio, simplified-text and low-bandwidth variants are generated and instructor-approved before release — eliminating per-learner inference cost, though no prototype is reported.

Common Misconceptions

"If a platform is effective in principle, students will use it." Capability and take-up are separate problems, and take-up is often the binding one. In a two-year cluster RCT, **96% of students tried Khanmigo** — near-universal adoption — yet the median student messaged it in only **17% of sessions where they made a mistake**, the exact moment the tool was built for. A platform that logs the class has not changed it.

"Adoption is measured by logins." The informative gap is at message level, not account level. In that same trial only **~14.5% of messages carried a genuine mathematical question**. Ninety-six percent of students created the access event; roughly one in seven of their interactions did the intellectual work. Reporting a logins figure here would have described a success that did not exist.

"Open versus proprietary is a licensing detail that does not affect outcomes." The platform model shapes what institutions can do with the system: open platforms such as OATutor — an MIT-licensed adaptive tutor with a Creative Commons algebra content library, Knowledge Tracing mastery estimation and built-in A/B testing — let a department instrument and modify its own Pedagogies and Teaching Strategies, which a closed platform cannot. The license determines who may conduct the experiment.

"A platform that works at one institution will work as adopted." Platform effects run through local governance: privacy-first architecture, data minimisation, auditable logs and role-based access are what make an AI-integrated platform deployable at all, and they are institutional decisions rather than features you can infer from a vendor demonstration.

AI in the disciplines

Subject areas

AIEd in the Disciplines

> **AIEd in the Disciplines** — the application of artificial intelligence to teaching and learning within specific academic subjects, where each discipline's signature pedagogies, methods, theories, and concerns shape how AI is designed, used, and evaluated. Rather than treating AI in education as a single generic phenomenon, this overview organizes the knowledge base's discipline-specific coverage and surfaces the cross-cutting themes that run through subject-area AIEd research.

Questions to Consider

- A math tutor that excels at right/wrong feedback may fail in the humanities, where interpretation and authorship matter more than correctness. How does your own discipline define what counts as 'good feedback'?
- Research across 560 students found that disciplinary affiliation predicts how often and openly students use generative AI. Why might a discipline act as a whole 'activity system' shaping AI use — rather than AI being a neutral tool everywhere?
- The 'cognitive act' being offloaded to AI is discipline-specific: computation in math, code in CS, composition in writing. If over-reliance looks different in each field, how would you detect it in yours?
- What does AI mean for a discipline whose signature pedagogy is hands-on laboratory work, or interpretive meaning-making, rather than Problem Solving? Is there any subject where AI should play little role?
- Several disciplines — law, history, the arts — remain thin in AI-education research. Which discipline's AI use most deserves attention, and what would good AI in that field have to honor that generic tools don't?

Introduction

AI in education manifests differently across disciplines because each field has its own signature pedagogy — the distinctive ways knowledge is constructed, practiced, and taught. AI tutors that shine in mathematics may fail in the humanities, where interpretation and authorship matter more than right answers. This page is the umbrella map for those discipline-specific strands, which now run from school subjects through professional and applied training to studio practice. One member of the strand is not a taught subject at all: Learning Sciences is the research field around AI in education, supplying the mechanisms AI systems operationalize and the standards by which they are judged — it takes the cross-cutting view, against this page's premise that subject matter is what changes what support should do.

Discipline-specific concepts

The knowledge base has dedicated concept pages for several subject areas:

- **Math Education** — AI tutoring, adaptive problem-solving, and conceptual diagnosis in mathematics.
- **Physics Education** — AI simulation, chatbots, and problem-posing in physics learning.
- **Chemistry Education** — AI in laboratory/experimental design, AI-mediated formative assessment, context-based and inquiry-based instruction, Large Language Models (LLMs) technical limits on chemistry tasks, and the philosophy of experimentation.
- **Biology Education** — AI in laboratory instruction, AI literacy embedded in biology curricula, critical thinking in the AI era, and specialized tools (species identification, bioimaging, predictive modeling).
- **CS Education** — AI for code generation, debugging, and novice programming support.
- **Information Technology Education** — the applied wing of computing, preparing practitioners to select, secure, administer, and govern the deployed systems organizations run: its unit of analysis is the deployed system and the practitioner's judgment about it, where computer science education takes the program and the algorithm as its objects.
- **Writing** — AI-assisted composition, automated essay scoring, and writing feedback.
- **Language Learning** — AI interlocutors, pronunciation feedback, and conversational practice in second/foreign languages.
- **English Education (EAP / EFL / ESL)** — English for Academic Purposes (EAP) and English language teaching (EFL/ESL/L2): academic-English register, genre-based writing, and English-specific feedback and assessment — distinct from general language learning and general writing.
- **STEM Education** — the cross-disciplinary umbrella for science, technology, engineering, and mathematics.
- **Teacher Education** — the preparation and professional development of teachers (pre-service and in-service), a discipline in its own right whose AI research centers on teacher AI literacy, intelligent-Technological Pedagogical Content Knowledge (TPACK), and readiness to integrate AI.
- **Medical and Health Professions Education** — clinical simulation, Reinforcement Learning training, and foundational learning principles in health-professions education.
- **Nursing Education** — the densest empirical record in the clinical strand: simulation with virtual patients, LLM reasoning support, and adaptive platforms, framed around professional-identity formation as much as competence, and narrow enough to name the boundary where AI's documented benefits stop (complex psychomotor skill and emotionally loaded interaction) rather than treating health professions as one case.
- **Vocational Education and Training** — initial preparation for named trades and technical occupations, organized by qualification frameworks and assessed on what learners can do with equipment. It extends beyond the professional training and workplace upskilling that Workplace Learning covers to those not yet employed, and its recurring design question is which expensive-to-staff parts of practice AI can absorb without displacing the repetition that produces competence.

- **Design Education** — studio-based professional formation in product, service, interaction, interior and architectural design, where visible process is the assessed object and where generative tools make the polished artifact cheap: it narrows the studio disciplines that Arts, Design and Media Education covers to the professional design pipeline, so that critique, portfolio and regulation rather than material and performative practice carry the argument.
- **Engineering Education** — professional formation, design and hands-on learning, ethical use of AI, embodied assessment, and workforce preparation in engineering.
- **Business Education** — AI in business, economics, and management education: student-informed GenAI frameworks, curriculum integration via constructive alignment, and preparation for AI-integrated professional practice.
- **Humanities and Social Science Education** — interpretive cognition, authorship, and meaning-making in humanities and social sciences.
- **K-12** and **Higher Education** — education about and with AI at each level.

Cross-disciplinary themes

Several threads cut across all disciplines, though they play out differently in each:

- **Discipline as an activity system.** Jiang et al. (2026) show, across 560 undergraduates in five academic domains, that disciplinary affiliation is significantly associated with students' GenAI **usage frequency and disclosure practices** — disciplines function as activity systems whose norms, policies, and role expectations shape how students engage with and disclose GenAI. This is direct evidence for the knowledge base's premise that AI in education is not discipline-neutral.
- **The shape of "interdisciplinary" itself is discipline-determined.** Xia et al.'s (2026) PRISMA review of 59 studies catalogs six forms of interdisciplinary education in which AI features: STEM integration (n = 26), cohorts with cross-disciplinary student backgrounds (n = 14), non-STEM fields (n = 10), cross-disciplinary learning content (n = 10), inter-STEM integration (n = 8), and STEAM (n = 2). The distribution is a discipline-level finding, not a tool-level one: AI-supported interdisciplinarity is overwhelmingly STEM-hosted, and cohorts with cross-disciplinary backgrounds are studied more often than the non-STEM fields those cohorts are meant to bridge. The review further shows that the same AI functions recur across these settings — assistant (n = 43), evaluator (n = 22), agent (n = 14), monitor (n = 9) — while their cognitive, behavioral and affective effects differ by discipline and stakeholder, with students by far the most studied (n = 57), teachers next (n = 26) and administrative staff barely examined at all (n = 4).
- **Tutoring and feedback.** AI tutoring systems (AI Tutoring, Intelligent Tutoring, Feedback, AI Feedback Quality) appear in nearly every discipline, from math and physics tutors to writing and language feedback. The discipline shapes what counts as good feedback — right/wrong in math, argument quality in writing, fluency in language.
- **Assessment and evaluation.** Automated Assessment, Automated Grading, Automated Essay Scoring, and Formative Assessment are reimagined by AI across disciplines, but the scoring constructs differ (procedural accuracy vs. interpretive depth vs. communicative competence).

- **Cognitive offloading and over-reliance.** Cognitive Offloading and Over-Reliance risk appears across math, CS, and writing, though the "cognitive act" being offloaded is discipline-specific — computation vs. code vs. composition.
- **AI literacy and critical use.** AI Literacy, Critical Thinking, and Critical Pedagogy underpin responsible use in every subject.
- **Disciplinary grounding gates AI-supported Metacognition.** In a text-linguistics seminar, novices reflected metacognitively with LLMs chiefly where subject knowledge was already consolidated, and most attributed poor outputs to the model rather than their own prompt — evidence that prompt design must be taught explicitly within a discipline (Brocca & Garassino (2026)).
- **Equity and access.** Equity, Digital Divide, and Culturally Relevant Pedagogy concern all disciplines.

Signature pedagogies, methods, and theories by discipline

Each discipline brings distinctive pedagogical traditions that AI research engages:

- **Physics** — model-based reasoning, experimentation, and Simulation. AI research uses virtual labs (Ben-Zion), chatbots (ChatGPT typology), and problem-posing (GenAI problem-posing).
- **Chemistry** — abstract submicroscopic concepts, specialized notation, and laboratory practice. AI research spans AI-supported experimental design (AI-designed lab manuals), context-based 7E instruction with AI tutoring (context-based + AI), AI-mediated formative assessment (instructor–AI roles), and the philosophy of experimentation (philosophy of experimentation).
- **Biology** — specialized terminology, systems/visual-spatial thinking, and hands-on laboratory and fieldwork. AI research spans virtual lab teaching assistants (ChatGPT as VTA), AI literacy embedded in biology curricula (AI literacy in a biology class), ChatGPT in challenge-based learning (ChatGPT in CBL), critical thinking in the AI era (critical thinking in bio sciences), and the AI-tools landscape (AI tools review).
- **Writing** — process-oriented, recursive drafting and revision. AI research spans AI as writing coach, automated scoring, and stage-based ownership (ownership stages).
- **English education (EAP/EFL/ESL)** — English as target language and academic register. AI research spans ethical EAP integration (Alharbi et al.), GenAI EAP writing revision (feedback-literacy scripts), EAP reading-material adaptation (differentiated EAP materials), ESL tutoring (TACT), and English-specific assessment (self-referential L2 writing evaluation, EFL assessment).
- **Teacher education** — a discipline whose AI research centers on preparing teachers to integrate AI: intelligent-TPACK frameworks (i-TPACK PD), teacher AI literacy (science educators), pre-service readiness (intelligent-TPACK readiness), and in-service trust and ethics (trust and ethics).
- **Humanities & social sciences** — interpretation, authorship, and critical meaning-making. AI research foregrounds interpretive cognition (Voicu) and the philosophy of AI rather than tutoring for correctness.

Represented disciplines in the knowledge base

The knowledge base's strongest discipline-specific coverage is in **STEM** broadly — particularly **Math Education**, **Physics Education**, **Chemistry Education**, **Biology Education**, and **CS Education** — followed by **Statistics and Data Science Education**, a strand distinct from mathematics because its signature pedagogy is the data investigation rather than reasoning toward a determined answer. An example of the strand's own design problem: DagFlow-AI uses an agentic pipeline to generate context-matched synthetic datasets, which addresses the material a statistics course needs rather than the explanation of it — and, on the authors' own account, cannot teach data collection, measurement or study design. and **Writing**, **Language Learning** (with a distinct **English Education (EAP / EFL / ESL)** strand for EAP/EFL/ESL), and more recently **Engineering Education**, **Teacher Education** (with a substantial body of pre-service and in-service AI-training research), **Medical and Health Professions Education**, and **Humanities and Social Science Education**. Engineering and design also have a growing body of articles. This concentration tracks the wider literature: Xia et al.'s (2026) review found STEM the most common interdisciplinary form in AI-supported higher education (n = 26), well ahead of non-STEM fields (n = 10) and STEAM (n = 2). The caution is discipline-level: AI-in-education evidence accumulates fastest where computational tooling is easiest to embed, not necessarily where AI's pedagogical value is greatest. The most recent additions broaden the strand past academic subjects into professional and applied education — nursing, information technology, and vocational education and training — where learners are assessed on demonstrated practice rather than on correctness, and where the employer and the licensing body, not only the academy, define what counts as competence.

The vocational strand is the thinnest in that evidence: a systematic review of 26 studies in vocational education and training found none conducted in workplace settings despite VET's work-based character, only five randomized experiments, and only three designs granting learners an active role (Deutscher et al. (2026)).

Underrepresented disciplines

Several disciplines remain thin in the knowledge base and are good candidates for future ingestion:

- **Law and legal education** — minimal coverage: LLMs and Italian legal exams.
- **Psychology and counseling** — few AI-in-education articles: AI feedback literacy, critical GenAI use, virtual patient psychotherapy training.
- **History** — only isolated articles: LLMs and historical reasoning.
- **The arts (visual art, design, music)** — emerging coverage: AI in interior design education, GenAI in architectural design studios, AI vocal pedagogy, AI in music education, text-to-image competence paradox. The design-side studies in this list now have their own home: Design Education draws the architectural, interior-design and text-to-image studio work into a page about professional design formation, leaving visual art, music and performance as the thin remainder.

These underrepresented disciplines would benefit from dedicated concept pages and additional article ingestion as the knowledge base grows.

Common Misconceptions

- **“Discipline matters mainly for content examples.”** Research across **560 students** found disciplinary affiliation **predicts how often and openly students use** generative AI. Discipline shapes whether the tool is used at all and whether that use is disclosed, not only what it is asked about.
- **“Interdisciplinarity is a generic institutional goal.”** The **shape of “interdisciplinary” is itself discipline-determined**: Xia et al.’s (2026) review finds the form it takes varies by field. A single institutional definition misreads at least some of the disciplines it covers.
- **“Vocational education has a research base comparable to the academic disciplines.”** The vocational strand is **the thinnest in that evidence**: a systematic review of **26 studies** in vocational education and training found **none conducted in workplace settings** — the settings where the competence is actually exercised. The literature’s absence is a gap, not a null result.

Math Education

> **Math Education** — the study of how students learn mathematics and how AI can support mathematics teaching, spanning affective tutoring, cognitive diagnosis from handwritten work, productive struggle evaluation, help-seeking behavior, teacher-AI collaboration for visual generation, and student-AI interaction trajectories. Math education is the most active domain-specific research area in this knowledge base, with 32 articles that collectively explore how AI can support — and sometimes undermine — mathematical learning from elementary fractions through higher education.

Questions to Consider

- Math problems have clear right answers yet require rich reasoning, which is why math is a favored testbed for AI tutoring. When you're stuck on a math problem, what kind of help actually helps you learn — an answer, a hint, or a question — and which is the AI likely to default to?
- Research finds AI tutors often default to over-helpfulness, rarely pushing for rigor even when students are ready. If you're designing a tutor, how do you decide when to withhold help to preserve the 'productive struggle' that builds understanding?
- The page shows students who request hints too early or skim them superficially tend to learn less. Have you ever reached for a hint out of impatience rather than genuine effort? What does that reveal about how AI support can undermine rather than support learning?
- AI cognitive-diagnosis systems sometimes hallucinate evidence and over-attribute mistakes, and even strong models underperform when reading students' actual handwritten work. How confident would you be in a tutor that diagnoses what you got wrong from your scratch work?
- LLMs flip their answers across mathematically equivalent problem formulations — the same problem presented differently changes the result. What does this say about using AI to score or diagnose math understanding?

Introduction

Mathematics education has become a primary domain for AI in education research because math problems have clear right answers yet require rich reasoning — making them ideal for studying tutoring effectiveness, assessment validity, and how AI tools interact with student cognition and affect. The articles in this knowledge base reveal both the promise of AI math tutors and persistent challenges: over-scaffolding that undermines productive struggle, hallucination in cognitive diagnosis, and the difficulty of balancing AI assistance with genuine learning.

Key research themes

AI math tutoring and scaffolding is the largest cluster, with four articles examining how AI tutors support or undermine math learning. **MathBuddy** demonstrates that adding affective awareness — detecting student

emotions from text and facial expressions — produces a +23-point win rate advantage in math tutoring, connecting to Affective Computing and Affective Tutoring. **TutorMoments** evaluates 462 teacher-annotated transcripts from grades 2-7 math tutoring and finds frontier models default toward over-helpfulness, rarely pushing for rigor even when students are ready — directly challenging the alignment between AI helpfulness and Scaffolding principles. **An et al.** analyzed 999 students across three semesters in the *Decimal Point* ITS, finding that premature hint requests and superficial hint reading consistently predict reduced learning gains, even after controlling for prior knowledge — a finding that connects to Help-Seeking and Learning Analytics.

Task design, not only tutoring. Analyzing 158 coded text units from 13 prospective primary teachers, Ledezma et al. (2026) found GenAI-designed geometry tasks reached for high cognitive demand yet wrote closed instructions, and one embedded a wrong scale (4 m drawn as 8 cm, stated as 1 m = 4 cm) (Ledezma et al., 2026).

A satisfaction penalty. Steering an LLM tutor through a Productive Failure plan instead of letting it answer raised strategy fidelity and produced 2.6 solution attempts per session in a 17-student high-school study, yet students rated the productive-failure tutor less helpful than a baseline (Puech et al. (2025)).

Socio-emotional support can buy efficiency rather than achievement. Adding an LLM mindfulness layer to a seventh-grade algebra tutor left learning and state-math anxiety unchanged between arms (42 of 252 students analyzed after disruptions), yet mindful-condition students reached comparable learning with less time and fewer requested hints (Rief et al., 2026).

Pooled across subject domains, GenAI's effect on learning motivation was largest in language ($g = 0.946$) and moderate in mathematics ($g = 0.711$, 95% CI [0.356, 1.066], $k = 4$), so the motivational case for GenAI in mathematics rests on a small, exploratory subgroup rather than a stable effect (Fang et al. (2026)).
Offloading inside mathematics homework. Chatlog traces from 23 linear algebra students show the prompt mix moving with the task while 90% of submissions stayed close to the model's output, and a 153-student proof course found AI-supported homework gains with no exam gain (Kontorovich & Wallach (2026); Chen et al. (2026)).

Cognitive diagnosis and assessment explores AI's ability to evaluate math thinking. Razavi and Powers (2026) add a large-scale item-difficulty study spanning both math and reading: across 5,170 K-5 items calibrated under the Rasch IRT model, GPT-4o's zero-shot difficulty ratings correlated moderately-to-strongly with true difficulties ($r = 0.83$ math, $r = 0.81$ reading) but were uneven across grades, while a feature-based approach (LLM-extracted features into tree-based models) reached correlations up to $r = 0.87$, with grade level and word count the top predictors. The study offers a practical seven-step workflow for testing professionals and cautions that generalizability beyond K-5 math and reading is unclear. **MathCog** benchmarked 18 LLMs on 3,036 teacher-annotated diagnostic verdicts from handwritten math work, finding all models severely underperform ($F1 < 0.5$) with systematic over-attribution and hallucination of evidence — connecting to Knowledge Tracing, Hallucination Risk, and Multimodal AI assessment challenges. **Nath et al.** showed that Large Language Models (LLMs) math Problem Solving is highly sensitive to surface representation — models flip correctness across equivalent problem formulations — raising Assessment Validity concerns for AI-based math scoring. **Olaoye, Owolabi and Olaoye (2026)** show a contrasting route to evaluating mathematical responses: their Automated Extended Essay Grading Software scores extended-response mathematical items in a senior-secondary Economics examination by semantic similarity against

the WAEC marking scheme, with no training on graded scripts. It agreed with 12 human examiners at an intra-class correlation of 0.863 (average measures), with Pearson coefficients from 0.604 to 0.864. The agreement sits where the marks are lowest — the software averaged 5.94 out of 20 against 5.97 for the raters, each examiner marked only 84 of the 1,008 scripts, and the authors attribute the low scores to candidates' unfamiliarity with computer-based answering.

Student engagement and AI literacy examines how students interact with AI math tools. **Abdelghani et al.** traced temporal trajectories of student-AI interaction in math learning, identifying a developmental path from superficial prompting to "epistemic proactivity" — active, self-directed pursuit of conceptual understanding. This connects to AI Literacy, Metacognition, and Self-Regulated Learning. **Holman** found that AI-adaptive platforms significantly improved fraction comprehension for students with math learning difficulties, connecting to Personalized Learning and Adaptive Learning.

Teacher support explores AI tools for math educators. **Simulated-student role-play** also serves teacher practice: Zhuang and Zhang (2025) built *Student GPT*, a custom ChatGPT chatbot that role-played a middle school student holding common ratio-reasoning Misconceptions about AI, giving preservice secondary math teachers low-risk practice at diagnosing and guiding student thinking toward correct solutions. The setup illustrates GenAI-powered Simulation as a complement to costly platforms like TeachLivE for building pedagogical content knowledge about student misconceptions.

Pre-service teachers can explore with GenAI but not yet validate it. In an Abstract Algebra course, 13 of 18 pre-service mathematics teachers were adequate at constructing examples and non-examples, while 14 of 18 sat at the two lowest levels for judging whether an AI response was valid (Nurlaelah et al. (2026)).

Classroom AI tools also create orchestration work the older typology does not name: observing six high-school mathematics lessons found teachers monitoring dashboards, correcting the AI's wrong Feedback, and mediating its output for the class, with content and ethical judgment most visible when fixing an AI error (Noh & Kim, 2026).

The knowledge base's only field-level synthesis of this domain is a 2021–2025 PRISMA review of 42 studies screened from 922 records (Cohen's kappa = 0.88), and it adds a category the page's clusters otherwise lack: teacher-facing automation, where MATH41 supports rapid production of mathematics tasks for learners at different levels. The hybrid model CognifyNet then analyses students' activity patterns so educators can detect emerging difficulties early. The same review locates the field's blind spot — with Education at 60% and Computer Science at 28% of study domains, only one study fell in Psychology, leaving emotional impact, trust and ethics comparatively underexplored — and insists that technical capability should not be equated with demonstrated classroom effectiveness. (Artificial intelligence in mathematics education: A PRISMA-based systematic literature review (2021-2025))

Inclusion is a design property, not a byproduct of capability. A review of 38 sources pairs UDL with SAMR and finds that AI can redefine a mathematics task while leaving it inaccessible to students whose language, device, or connectivity does not fit (Jita, Jita & Omoniyi, 2026).

The domain's challenge ranking puts teacher capacity first. A second systematic review, of 54 studies from 2017-2025, counted technological–pedagogical integration and teacher readiness in 38, equity and access risks in 34 and limits to deep reasoning in 29, and links them to instructional responses in a three-dimensional framework (Manto et al. (2026)).

Higher education math explores AI's impact on advanced math practice. **Bui et al.** applied socio-cultural theory to GenAI in university mathematics, analyzing AI as a "runaway object" that transforms academic practice in ways that outpace institutional and pedagogical norms.

Symbolic obstacles in calculus are representational rather than procedural: graph-to-symbol translation was the dominant obstacle, and after an AI-supported sequence coded symbolic errors fell by 27.4%–53.8% (Nursit et al., 2026).

LLM tutoring and instructional design is an emerging cluster of two 2026 studies that sharpen the math-education evidence base. Looi, Liu, and Sun (2026) developed a rule-guided LLM tutoring system for primary-school math word problems whose three-layer architecture (diagnosis → intent selection → constrained response generation) improved interactional consistency and reduced premature answer-giving in a 40-student Grade 5 classroom pilot — evidence that procedural math domains need structured rule-guards on otherwise stochastic LLM scaffolding. Zhu, Liang, Mao, and Wang (2026) applied a smart-classroom model to mathematics M.Ed. students and found statistically significant gains ($p < .05$) in instructional-objective design across curriculum-standards, textbook, and student-condition dimensions.

Prompt design is itself a measurable lever: on the MathDial benchmark a pedagogically informed Socratic "Tutor Prompt" raised Success@N and sharply cut Telling@N relative to a base prompt for both GPT-4o and GPT-4o-mini (Chudziak & Kostka (2025)).

GenAI for mathematical modeling tasks extends the generation strand beyond routine exercises. An AI-powered platform developed through the ADDIE approach used direct variation in secondary school mathematics as an illustrative topic, addressing teachers' lack of time and resources to design high-quality modeling tasks: existing tools typically produce conventional word problems or routine exercises, whereas the platform aimed to generate resources that foster mathematical modeling competencies, grounded in established design principles and retrieval-augmented generation. - **Visual chain of thought: the autonomy gap in geometry.** GeoVAD-Bench diagnoses intermediate visual aids rather than final answers across 600 auxiliary-construction problems (200 easy, 200 medium, 200 hard), and finds a consistent pattern: supplying the reference auxiliary diagram improves accuracy modestly (+3.3, +3.0, +7.0 points across three models) while leaving the model to construct its own auxiliary line on the way to the correct answer widens the gap by 10.0 to 13.5 points, with two models performing worse than when they had no visual reasoning at all. Four process-error categories accounted for 93.1% and 89.7% of attributed failures. For Problem Solving instruction the finding is that diagrammatic scaffolding has to be trained and evaluated separately from answer accuracy. (Beyond Generation and Accuracy: Diagnosing and Enhancing Visual Chain-of-Thought for Geometry Problem Solving) - **AI-susceptible problems lose study time and retention.** A ten-year panel of 3.2 million ALEKS interactions found learning time on text-based word problems — those most transcribable into AI prompts — fell 26.9% after ChatGPT's release, while proctored retention items showed a 25% decline in the odds of a correct response (Rismanchian et al., 2026).

- **Students value immediate feedback, but optional practice platforms go unused.** Of 157 students, Chen et al. (2026) saw 95 register and only 34 attempt a question; users rated engagement highest (79% agreement) while just 42% preferred the platform to the existing problem booklet.
- **Errors become the mechanism.** Embedding AI in a mastery-based practice platform slowed progress — students attempted fewer questions — yet raised next-attempt correctness after

mistakes, while a three-correct-in-a-row mastery rule lifted platform success without improving delayed learning (Oreopoulos et al. (2026)).

- **AI can raise achievement while widening a gender gap.** In a six-week quasi-experiment with 115 Nigerian senior-secondary students, ChatGPT feedback raised quadratic-equation achievement over conventional teaching (29.18 vs 24.06), yet male students outperformed female students (30.95 vs 25.16) despite no gender difference in Self-Efficacy — an equity caution for AI mathematics support (Oladayo & Diri, 2026).
- **Students still prefer the teacher's grading decision.** In a vignette experiment with 250 seventh-grade students, teacher-made decisions on a mathematics exercise drew higher acceptance than AI-made ones (M = 4.48 against M = 3.47), perceived fairness carried 67.52% of the effect, and written explanations widened rather than closed the fairness gap (Zhang, Fan & Qi (2026)).

Connections to related concepts

Math education sits within the broader STEM Education domain with distinctive connections to Intelligent Tutoring and AI Tutoring through the strong tradition of cognitive tutors and ITS research in mathematics, to Scaffolding through the productive struggle and hint-use literature, to Affective Computing through math anxiety and emotion-aware tutoring, to Knowledge Tracing and Assessment Validity through cognitive diagnosis and assessment research, and to Teaching through teacher-AI collaboration in math instruction. The K-12 connection is particularly strong — many of the math articles involve K-12 contexts — while Higher Education connections emerge in teacher preparation and advanced math practice.

Implications for math instructors

- **Treat AI tutoring as a help-seeking lever, not a capability fix.** Hint-use research shows premature hint requests and superficial hint reading predict lower gains — so the design of *when and how* students seek AI help matters more than raw tutor capability. Encourage students to attempt before asking, and surface help at the moment of need rather than on demand.
- **Protect productive struggle.** TutorMoments finds models default to over-helpfulness, rarely pushing for rigor; configure AI support to scaffold rather than solve, and monitor for answer-replacement that erodes reasoning.
- **Do not treat AI diagnostic output as ground truth.** MathCog shows LLMs underperform at diagnosing math thinking (F1 < 0.5) with over-attribution and hallucinated evidence; use AI diagnosis as a suggestion to verify against the student's actual work.
- **Beware surface-format fragility in AI scoring.** Representation sensitivity means equivalent problems can flip AI answers — a validity risk for AI-based math assessment; prefer human review for high-stakes scoring.
- **Use AI to lower the bar for personalized practice.** Adaptive platforms improved fraction comprehension for students with math learning difficulties; deploy AI-adaptive tools selectively for learners who need differentiated support.
- **Keep the teacher in control of AI-generated instructional materials.** Teacher control of AI visuals supports a framework that balances AI efficiency with pedagogical correctness.

Common Misconceptions

“The motivational case for AI in mathematics is as strong as for language.” The pooled evidence is thinner for mathematics and should be read that way: GenAI’s effect on learning motivation was largest in language (**g = 0.946**) and moderate in mathematics (**g = 0.711, 95% CI [0.356, 1.066], k = 4**). Four studies and a confidence interval spanning most of the plausible range is a weak basis for a strong claim, and the domain difference is large enough that language findings should not be carried across unexamined.

“If the homework looks right, the mathematics was done right.” Chatlog traces from **23 linear algebra students** show the prompt mix shifting with the task while **90% of submissions stayed close to the model’s output**, and a 153-student proof course found AI-supported homework performance diverging from unassisted assessment. Proximity to the model’s output is the measure of having been helped, not of having learned; in a domain with clear right answers, a correct submission is the least diagnostic artifact available.

“Mathematics is an easy domain for AI because the answers are checkable.” Checkability is what makes mathematics a good testbed, not what makes it safe. Because the final answer is verifiable, a student can validate a solution they did not construct — which is precisely how the subject’s reasoning gets bypassed while the grade stays clean. The property that attracts researchers is the property that makes offloading invisible.

“Item difficulty for mathematics can be assigned by a capable model.” It has to be calibrated against responses. In an item-difficulty study spanning **5,170 K-5 items** calibrated under the Rasch IRT model, model-generated zero-shot difficulty ratings were compared against empirical calibration precisely because stated difficulty and measured difficulty are different quantities.

Statistics and Data Science Education

> **Statistics and data science education** — teaching learners to reason about data: framing a question, planning a study, collecting and inspecting data, analyzing it, and communicating what the evidence will and will not support. In AI in education it shares the Math Education focus on reasoning with right and wrong answers, but its signature pedagogy turns on the **material**: the dataset, the chart, the code. That is why the distinctive AI question here is rarely "can the model explain a concept" and more often "can it produce or scaffold the artifact the lesson runs on". Those artifacts are a synthetic dataset with knowable structure, a tactile chart a blind student can read, a practice question whose stated difficulty is honest, an R tutor that withholds the answer. Because the artifact can now be generated, the discipline's central risk is that generated artifacts carry claims nobody validated.

Questions to Consider

- When a statistics course uses a generated dataset, what does a student learn about where data come from — and does it matter that the answer is "nowhere"?
- An LLM labeled practice questions Easy, Medium and Hard. Its labels tracked the Bloom's levels it invented alongside them almost perfectly, and correlated essentially zero with how students actually performed. What would make a difficulty label trustworthy?
- Statistics is often the course where students first meet authentic data problems. If AI supplies the data and the analysis Scaffolding, which part of that encounter is left?
- Is statistics education a branch of mathematics education, or a separate discipline with its own pedagogies? Does your answer change what AI should be built for it?

Introduction

Statistics and data science education covers the investigative cycle as a teachable object — the Guidelines for Assessment and Instruction in Statistics Education (GAISE) recommendations and the Problem, Plan, Data, Analysis, Conclusion (PPDAC) framework are the field's two standard maps of it. Its pedagogies differ from mathematics education in a way that matters for AI design: mathematics instruction evaluates reasoning toward a determined answer, while statistics instruction evaluates reasoning through an **investigation**, where the data, the design, and the limits of inference are themselves the content. The knowledge base files this page separately for that reason. Statistics sits beside mathematics in the curriculum and draws on it, but a tool built to check a derivation is answering a different question from a tool built to generate a dataset whose relationships a student must discover.

The articles here share a pattern that follows from the discipline's artifact-centredness. AI appears as a producer or scaffolder of the lesson's material rather than as an explainer of its concepts: a purpose-built tutor for R, a pipeline that generates tactile charts, a generator of synthetic datasets, an audit of auto-generated practice questions. That shape makes the evidentiary question sharper than in most disciplines,

because when the artifact is generated, every claim embedded in it — a difficulty level, a coefficient sign, a distribution — was decided by something other than the instructor.

Why a separate page from math education

Math Education carries the knowledge base's largest discipline strand and covers reasoning, Problem Solving, affective tutoring and cognitive diagnosis. Statistics and data science education overlaps it on prerequisite skills and shares the STEM Education umbrella, but its signature pedagogy is the **investigation**, and its characteristic failure mode is a validity failure rather than a correctness failure. A student who computes a correct mean from the wrong sample has done the arithmetic right and the statistics wrong, and the assessment frameworks this field teaches — validity, sampling, the scope of a conclusion — are built to catch exactly that.

Treating the two as one page would obscure the distinction that the evidence keeps returning to. The corpus's data science studies are about **generated material and its calibration**: an R tutor's adoption curve, practice questions whose metadata does not match student performance, datasets whose relationships are asserted rather than observed, charts whose design parameters are derived from perception research. None of those is a mathematics-education problem.

The boundary is not clean at the edges. Statistical programming sits inside CS Education in most institutions, and several articles here are filed there; accessibility work on statistical graphics overlaps Special Education and accessible design; responsible data science overlaps CS Education and Ethics. The page is a home for the cluster, not a claim that the cluster is sealed.

Lund and colleagues (2026) mark that overlap from the curriculum side: four accountability pillars (answerability, responsibility, enforcement, reflexivity) crossed with four XAI dimensions, taught through graded model cards, LIME and SHAP explanation audits, and impact assessments, with the authors conceding that explanation is not accountability.

Generated artifacts and the validity question

The sharpest evidence in this strand is a construct-validity audit of LLM-generated retrieval practice in three data science courses. Across a 10-week study the model's Easy, Medium and Hard labels tracked the Bloom's levels it had generated alongside the questions almost perfectly, and were essentially unrelated to how students actually performed on them. The labels described question formatting, not difficulty, which makes validity the operative concern: generated item metadata has to be calibrated against student response data before an instructor trusts it, and the correlational structure that makes it *look* coherent is generated by the same model in the same step. The same study found students used LLMs heavily for debugging and concept questions and reported high satisfaction, while their perceived deep-learning benefit declined over the term — satisfaction and learning moving apart in the same classroom.

A second strand asks what happens to the data itself. Synthetic data generation is presented as a route to personalization: matching a dataset to a student's interests, the learning objective, and their skill level is a three-way constraint real datasets rarely satisfy. The design that follows from it is to have language-model agents specify an explicit data-generating mechanism — variables, a directed acyclic graph, distributions, formulas with coefficients — which a program then executes, so the process is inspectable and reproducible

rather than an opaque generator. The limit is stated by the authors themselves: synthetic data cannot support conclusions about the world or teach data collection, measurement and study design, so the approach complements real data rather than replacing it. That limit is not incidental to statistics education. It is the part of the cycle PPDAC puts first and second.

Scaffolding the tools of the discipline

The clearest positive results concern tools built for a specific course and a specific language. A purpose-built AI tutor wrapped around a hosted API, system-prompted to guide rather than answer, was deployed in a semester-long R programming course for psychology undergraduates: 76% to 84% of students used it in exam-relevant weeks. They self-reported spending 53% of their study-tool time with it against 8% for unvetted generative AI tools, use fell to 50% to 58% once weekly content stopped counting for the exam, and rebounded to 64% in the week before the oral examination. Adoption tracking the assessment calendar that closely is a reminder that tool uptake is a study-behavior phenomenon, not only a quality signal.

Scaffolding quality matters independently of access. An experimental comparison of guided against unrestricted Large Language Models (LLMs) access found that explicit training in reasoning-focused scaffolding — stepwise hints, verification — produced better independent performance and better Self-Assessment calibration than uncritical reliance, which locates the educational work in the structured interaction rather than in the model. The accessibility strand makes a similar move for the artifact: a roughly 1,500-line JavaScript pipeline derives tactile design parameters from plate dimensions, offers five modular chart builders, and produces print-ready STL in under 250 milliseconds with single-pass Braille and English labeling. Optionally it uses a Multimodal AI model to extract chart specifications from an uploaded image, with mandatory teacher review before printing. Generation is paired with a human check in both designs.

What the evidence does not yet establish

- **No learning-gain evidence for generated datasets.** The synthetic-data design is demonstrated through a single case study with no student users and no comparison against a real dataset or against an instructor hand-building a generator.
- **No validated difficulty or quality metadata.** The one audit found generated labels uncorrelated with performance, so the field has a demonstration of the failure rather than a working calibration method.
- **Adoption is not learning.** The R tutor evidence is usage, self-report and prediction, from 49 pretest and 34 posttest respondents in one course at one university.
- **Most scaffolds are single-site and un-replicated**, and the responsible-data-science curriculum framework is described by its authors as conceptual and untested.
- **No study tests transfer to real-data practice**, which is the outcome the discipline actually cares about: whether a student who learned on generated material can investigate real data.

Implications for AI in education

1. **Calibrate generated item metadata against response data before trusting it**, because coherent-looking labels can be generated by the same model that wrote the questions and carry no information about difficulty.
2. **Keep generated artifacts inspectable.** Where a mechanism can be specified — a DAG, a distribution, a formula — specifying it is better than sampling from a black box, both pedagogically and for the instructor's ability to verify what students will find.
3. **Do not let synthetic material crowd out measurement and design,** since those are the parts of the investigative cycle a generated dataset cannot teach and the parts GAISE and PPDAC place first.
4. **Build the human check into the pipeline,** as the tactile-graphics work does with mandatory teacher review before print, rather than treating generation as the end of the process.
5. **Read usage as a study-behaviour signal.** Adoption that tracks the exam calendar is evidence about incentives, so evaluating a discipline-specific tool requires outcomes measured after the incentive disappears.

The material itself is a design problem, not only the explanation. A statistics or data-science course needs datasets that fit the student's question, and generating them is where AI enters some of this strand's work: DagFlow-AI is an agentic pipeline producing context-matched synthetic datasets, with a worked case of matching the data to a student whose interest was climate and health while holding objectives and skill level fixed. That is situated learning applied to the material rather than to the explanation. The authors are also explicit about the limit: synthetic data cannot teach data collection, measurement or study design, so the strand's signature pedagogy is only partly reachable this way.

Common Misconceptions

- **"Satisfaction and perceived benefit indicate a data-science AI tool is working."** Students used LLMs heavily for debugging and concept questions and **reported high satisfaction, while their perceived deep-learning benefit declined over the term**. Satisfaction held and the self-assessed learning trajectory fell, so neither figure alone is the outcome.
- **"An unrestricted model is as good as a guided tutor."** The gain came from scaffolding training — explicit instruction in stepwise hints and verification — which beat plain access to the same model on independent performance and on self-assessment calibration. The guidance, and the training in how to use it, carried the effect.
- **"Guarding against answer-giving is enough."** A course-specific tutor on a hosted API, instructed to nudge rather than supply answers, was adopted by **76% to 84%** of psychology undergraduates during exam-relevant weeks of a semester-long R programming course. That is adoption, not evidence that the guarding produced learning: prompt-level guarding is one lever among several and does not by itself produce learning.

Physics Education

> **Physics Education** — the study of how students learn physics and how to teach it more effectively, spanning Socratic AI tutoring, computational thinking assessment, student Trust and AI adoption patterns, automated scoring validity, and teacher preparation. The physics education articles in this knowledge base are notable for their domain-specificity: they explore how AI tools interact with the unique cognitive demands of physics reasoning — visual-spatial thinking, mathematical modeling, abstract systems thinking, and multi-step Problem Solving.

Questions to Consider

- Physics problems often require visual-spatial thinking, mathematical modeling, and multi-step reasoning. Why might these be precisely the cognitive demands that current AI tutors struggle with?
- Students report a big trust-utility gap—91% use AI for coursework but only 41% trust it. Have you experienced using a tool you didn't fully trust? What drove the gap?
- AI scoring systematically underestimated linguistically weak students' physics explanations. What does that suggest about how an AI grades an explanation versus a correct numeric answer?
- One study found a Socratic AI chatbot dramatically improved question specificity in a live physics course, but students also frequently 'ceded strategic control' to the tutor. When does handing over strategic control help learning, and when does it harm it?
- Why might physics be a 'proving ground' for AI in education—what makes its problems ideal for studying how AI affects reasoning and assessment?
- Would you trust an AI to grade your physics problem set or reason through a force diagram with you? What would need to be true about the AI—and about your course—for you to say yes?

Introduction

Physics education research has become a proving ground for AI in education because physics problems are well-structured yet cognitively demanding, making them ideal for studying how AI tools affect learning, reasoning, and assessment. The 26 articles in this knowledge base collectively paint a picture of a field grappling with both the promise and the limits of AI — from Socratic chatbots that improve student question quality to systematic scoring biases that penalize linguistically diverse learners.

Key research themes

Socratic AI tutoring in physics is the most developed theme, with three articles deploying Large Language Models (LLMs)-powered Socratic dialogue in real physics courses. **Hashmi et al.** demonstrated that sustained Socratic interaction with an AI chatbot dramatically improves question specificity in introductory mechanics, with 150 STEM majors in a live course. **Hashmi & Rebello** built a bottom-up taxonomy of 357 student discourse categories from the same deployment, revealing that meta-procedural turns — where

students cede strategic control to the tutor — dominate student interactions. Both contribute to broader Socratic Method research and connect to AI Tutoring and Intelligent Tutoring frameworks.

Student AI adoption and trust explores how physics students actually use AI tools. **Fouad & Bentley** found a 50-point trust-utility gap: 91% use AI for coursework but only 41% trust it, with students spontaneously identifying AI failure modes in visual-spatial reasoning and circuits. **Becker et al.** developed a two-profile typology — 70% "Pragmatic Users" and 30% "Skeptical Non-Users" — from 1,189 survey responses, showing both groups make calculated risk-utility trade-offs. These studies advance AI Literacy and Trust Calibration research, and challenge one-size-fits-all AI policies.

Use is selective, and approval outruns it. In a survey of 209 engineering students at six Kazakh universities, 36.1% reported regular general AI use, but only 20.2% used it very frequently in physics and specialized disciplines (Nauryzbayeva et al. (2026)). Use concentrated on explanation-seeking tasks — 55.1% for clarifying difficult topics and 51.4% for homework — ahead of written assignments at 43.5%. Engineering thinking drew the strongest perceived contribution at 61.1%, yet the instrument measured only use patterns and perceived support, not learning. Nothing here shows that AI improved physics learning, and the authors say so.

Structured use, not merely adoption. The adoption studies above describe who uses AI and how much they trust it. A separate strand asks what instructional design should do with that use, and multi-institutional evidence on it has been scarce. **Paul et al. (2026)** ran the four-step Physics AI-Replication protocol in 11 algebra- and calculus-based sections at four institutions: identify a hard problem, get an AI explanation and solution, request similar practice problems, then solve them independently before checking.

Perceptions were consistent across campuses. Of 358 enrolled students, 235 were surveyed (65.6%); 90.9% credited improved conceptual understanding and 97.7% found the replicated practice helpful; post-engagement confidence averaged 7.18 on a 1–10 scale with institutional means from 6.86 to 7.52; and the dominant qualitative theme held between 60.6% and 67.6% at every site. Confidence tracked those two protocol benefits ($r_s = 0.37$ and 0.35) but not AI usage frequency ($r_s = 0.02$) — the variable the adoption literature usually measures.

Epistemological beliefs track chatbot-behavior preference. In a large calculus-based course, 52% of students preferred a chatbot beginning with guided inquiry and answering only when asked, and they scored higher on the EBAPS total ($p = 0.029$) — differences that did not survive a Bonferroni correction, making the association suggestive, not conclusive (Sirnoorkar and Mamidpalliwar (2026)).

Acceptance has now been modeled rather than described: a 340-student structural equation study of Grade 10 physics classes in Hangzhou explains 58% of the variance in intention to use DeepSeek. Its notable result is that beliefs about physics — utility value, expectancy, cost — predict how useful and how easy the tool seems, not only whether students intend to use it (Xue, Xu, Qi & Lu (2026)).

Perception change without behavior change is what O'Brien et al. (2026) add to this picture. A reflective lesson on how LLMs work, taught in a required first-year course for physics majors, raised skepticism sharply — agreement that LLMs can leave students with a false sense of confidence rose from 58% to 88%, and the belief that an LLM outperforms the average physics student fell from 54% to 32% — while convenience (71% agreement) and deadline pressure (65%) remained the dominant reasons for use. The lesson's limits are as informative as its effect: AI Literacy instruction shifted what students said about these

tools and not the pressures that make them reach for one, which is why an intervention of this kind belongs alongside problem and policy design rather than in place of it.

Problem posing turns the learner into the problem author: 76% of 49 physics students perceived a positive change in their GenAI interactions after prompt-engineering training, novices benefiting most, and about 68% viewed the technique positively as self-study (Dawson & Rebello (2026)).

Assessment and computational thinking examines how AI can evaluate physics learning. **Savage et al.** used LLMs to assess computational thinking growth in introductory physics, finding LLMs can scale CT assessment but struggle with complex constructs like Systems Thinking. **Feser & Tschisgale** demonstrated that AI scoring systematically underestimates linguistically weak students' physics explanations — a finding that connects to Assessment Validity, Bias Mitigation, and Equity.

An AI grader's disagreement can be a retrieval failure, not a reasoning gap. In experimental physics laboratory reports a dropped sign or misread axis may never reach the model, so document conditions — high-resolution PDFs, editor-written equations — cap any score, and processing belongs behind teacher verification (Abreu et al. (2026)).

Psychometric infrastructure for diagnostic assessment. Le et al. (2026) invert the usual AI-in-physics question: rather than asking whether a model can solve or grade physics, they ask whether the field's own research-based assessments can be made to diagnose it. Mapping FCI, FMCE and EMCS items onto 14 fine-grained learning objectives and fitting a DINA cognitive-diagnostic model to 24,394 posttest responses from 807 courses at 79 institutions via the LASSO platform, they built the Mechanics Cognitive Diagnostic — reported as the first cognitive diagnostic computerized adaptive test in physics. The FCI and EMCS fit well ($RMSEA^2 = 0.033$ and 0.022) while the FMCE fit only marginally (0.065), and the authors trace that misfit to instrument design rather than modeling: 42 of 43 scored FMCE items share scenario stems in chained sets, creating the local item dependence that DINA's conditional-independence assumption forbids (the FCI blocks 13 of 30 items; the EMCS none). Classification accuracy met the low-stakes formative benchmark for 19 of 22 objective–assessment combinations; the three failures were EMCS energy objectives whose items overlap by roughly 70 percent, so mastery of one cannot be separated from the others. The significance for physics teaching is that instruments courses already administer can be repurposed to deliver actionable, objective-level feedback *during* instruction rather than a retrospective posttest score — provided the diagnostic claims are pitched at the resolution the item bank can actually support.

Benchmarking multimodal AI on authentic physics problems. Chen et al. (2026) introduce **OmniPhys**, a large-scale Multimodal AI Benchmark (15,246 questions, 19,850 images) spanning middle-school through university-level physics from Chinese educational corpora. Unusually, it evaluates not just multimodal *input* comprehension but multimodal *output* generation — whether models can synthesize structured physics diagrams, a core component of authentic problem solving. Extensive evaluations reveal critical gaps in current multimodal LLMs, especially in complex reasoning and visual generation.

Instructional-design frameworks for AI-augmented instruction. **Kuhn et al.** propose the **AIRIS** framework (Activate–Inquire–Reflect with Intelligent Support) — a three-phase structure for cognitively activated AI use in physics: students predict and sketch expected outcomes before AI (Activate), delegate computational and representational steps to AI while critically comparing output to their own predictions (Inquire), and interpret, check consistency across representations, and reflect on what the AI contributed afterward (Reflect). Grounded in Self-Regulated Learning, Cognitive Load Theory, multiple external

representations, and Human AI Collaboration, it frames the central challenge as instructional design rather than cheating or tool choice, and calls for “withdrawal condition” experiments testing whether learning survives the removal of AI support. - **Teach critique of AI solutions with a rubric.** Twenty-four introductory physics lab groups that critiqued an AI solution with MAPS-guided reflection identified skipped numerical integration, undefined notation and qualitative-instead-of-quantitative plotting, while groups that only solved a related problem accepted the polished output or rejected it from their own misconceptions (Borse et al. (2026)). - **Energy preconceptions decide whether the AI becomes concept talk or a lookup.** Wang et al. (2026) ran fourteen pre-service teacher groups through energy forms and conservation in Go-Lab with an on-demand metacognitive chatbot. Groups whose members answered an energy pretest differently asked the same kinds of questions as matched groups, but put AI query negotiation at the center of their interaction network and sustained positive or neutral evaluation of its answers, while matched groups ran a linear query-then-read path. Concept confusion ran f = 87 against 36, with 88.9% against 57.1% case coverage.

Generative video as synthetic experimental data. Alvarado-Cruz et al. (2026) generate video scenarios with PixVerse, Grok Imagine and Pippit for three resistive-force regimes — constant friction, linear drag and quadratic drag — extract the kinematics with the Open Source Tracker tool, and fit the analytical models by non-linear least squares. The synthetic data agreed with the classical equations of motion and recovered physically meaningful parameters, and the recurring practical finding is that prompt specificity governs physical coherence: more detailed descriptions produced more coherent dynamics. The workflow mirrors experimental practice from model construction to quantitative validation, and reframes prompt formulation as a stage of experimental design rather than a convenience. What it does not yet demonstrate is learning: validation here is agreement between generated motion and the authors’ models, not students’ measurement judgment, so the approach inherits the validity question any generated data used as evidence must answer.

Bespoke simulations for the topics PhET does not cover. LLM-generated HTML/JavaScript models let instructors produce the simulation a course needs rather than the nearest published one, subject to technical and physical validation; in a pilot, 53 students in 26 pairs built and refined their free-fall models with no programming background required (Ben-Zion et al., 2025).

A reusable four-element prompt — tools, display, hand controls, optimization — lets a no-code teacher generate a browser-based AR simulation whose pinch-and-spread gestures drive the physics; in a 29-student pilot the gesture helped all 29 “feel” wavelength (mean 4.52) and 86% reported greater engagement (Levy et al. (2026)). **AI-generated instrumentation from a prompt.** A rotation lab generated by natural-language prompting of an AI assistant, with no manual coding, measured uniform and accelerated circular motion to within 1% of independent Tracker video analysis, letting instructors build the interface around their pedagogical variables rather than adapt to a precompiled sensor app (Suñer et al. (2026)).

Assisted performance vs. unaided knowledge in a redesigned course. A 2026 redesign of the introductory nuclear and particle physics course at Ruhr University Bochum (Mikhasenko et al.) allowed generative AI on ten deliberately AI-resistant, research-shaped homework sheets designed so that naive prompting would not suffice. Engagement and ambition were high — 24 of 42 students earned credit on all ten sheets, and one derivation filled more than two meters of blackboard — but an unaided 90-minute written exam was a “serious warning”: a mean of 20.6/80, with only two of 27 examinees reaching 40. The authors conclude that assisted performance and independently retrievable knowledge are distinct achievements that cannot be

assumed to train or demonstrate each other, and that physics courses must reserve some practice for unaided work — reinforcing the knowledge base's broader transfer evidence.

A 2026 PRISMA review of 11 empirical studies across six countries reaches the same conclusion at the level of the field: short-term gains from AI feedback and simulation did not persist into later examinations or transfer to independent performance (review of AI in university physics education).

Agent role design as an instructional variable. Wang et al. (2026) hold the model (DeepSeek R1), platform, and temperature constant and vary only the prompt-specified role: a teacher-centered agent answering authoritatively from a bounded textbook knowledge source, versus a student-centered agent configured as an empathic teacher with knowledge of students' understanding, scripted to diagnose the cause of Misconceptions about AI, name the relevant concept, and transfer to an analogous phenomenon. Across 59 high-school graduates working two conceptual items, the student-centered agent produced higher post-test scores (9.67 vs. 7.93; r = 0.38), lower extraneous and higher germane cognitive load, stronger flow experience (d = 0.92), and higher empathy perception (r = 0.53) — evidence that role framing, not just answer accuracy, is what makes a physics agent instructionally effective (Pedagogical Agent, Prompt Engineering). - **Benchmark scores understate what models can already do in physics.** Re-grading six widely used physics benchmarks with domain experts found that most of the reported shortfall was an artifact of defective items and restrictive automated graders: of 250 audited rejections, 143 (57.20%) were benchmark defects and 95 (38.00%) grader errors, with only 12 (4.80%) genuine model errors. Corrected, HLE-Physics mean@4 rose from 47.28% to 78.66% and CritPt from 32.29% to 87.50%. For physics instruction this cuts both ways: it means students can already obtain expert-level text solutions to many canonical problems, so assessment of physics reasoning needs to move toward items that resist benchmark contamination and toward process evidence rather than final answers. (How Good Are Frontier Models at Physics? Expert Re-Grading Reveals Broken Evaluations and Near-Saturation of Leading Benchmarks) - **AI grading can reproduce a high-stakes physics outcome without matching every part.** Grading 10,364 handwritten Olympiad and university pages, a multimodal LLM recovered the same five-student Olympiad team as examiners and correlated with totals at r = 0.93–0.96, but exact question-part agreement reached 70% — examiner-controlled second reading, not replacement (Pathak et al. (2026)).

- **Physics benchmarks can be curriculum-grounded and non-English.** Jahin et al. (2026) built 1,834 Bengali questions from the national Grade 9-10 physics textbook and a 1,760-node knowledge graph; one fixed fine-tuning recipe gained 5.5, 15.0 and 23.3 points at 0.6B, 1.7B and 4B parameters.

Connections to related concepts

Physics education sits within the broader STEM Education domain but has distinctive connections: to Socratic Method through the strong tradition of Socratic dialogue in physics problem-solving; to Computational Thinking through the increasing role of computation in physics; to Assessment Validity through the challenges of scoring physics explanations; and to Workplace Learning through Simulation-based preparation. The Student Experience and AI Literacy concepts are essential for understanding how physics students navigate AI tools, while Educational Measurement and Automated Grading connect to the assessment dimension.

Implications for physics instructors

- **Design for student trust, not just adoption.** Fouad & Bentley document a 50-point trust-utility gap (91% use, 41% trust), with students identifying AI failures in visual-spatial reasoning and circuits — create opportunities to expose and discuss these limits rather than assume acceptance.
- **Use Socratic AI to deepen question quality, but watch for strategic ceding.** Socratic chatbots improve question specificity, yet taxonomy research finds meta-procedural turns dominate — students hand strategic control to the tutor. Intervene to keep students the decision-makers.
- **A well-engineered tutor beat in-class active learning.** Kestin et al. (2025) found that 194 Harvard life-sciences students learned more from the course's own AI tutor than from research-based active-learning lessons covering the same content (median post-test 4.5 vs. 3.5), with higher reported engagement and Motivation, crediting expert-crafted prompts and platform-sequenced problems rather than the technology alone.
- **Structure AI use cognitively, not just permissively.** AIRIS (Activate–Inquire–Reflect) shows the value of having students predict/outline before AI, delegate computational steps while comparing output critically, and reflect afterward — treat AI integration as an instructional-design problem, and test whether learning survives AI removal. In a randomized trial with 95 undergraduates, 45 minutes of SRL-aligned training on mechanics problems lifted accuracy when students later revised electromagnetism items with a model: 69.3% of their incorrect answers became correct against 41.3% for untrained controls (d = 0.81) (Huang et al. (2026)).
- **Guard against scoring bias.** AI scoring systematically underestimates linguistically weaker students' explanations; use language-aware or human-moderated scoring for conceptual assessment.
- **Use simulated classrooms for teacher preparation.** Simulated multi-agent classrooms give prospective teachers rare practice responding to authentic student reasoning — a low-cost complement to live microteaching.
- **Reserve unaided practice and assessment.** The Bochum redesign (Mikhasenko et al. 2026) shows AI-permitted, research-shaped homework completed with high engagement can leave students far behind on an unaided exam (mean 20.6/80) — treat assisted performance and independently retrievable knowledge as distinct, and build deliberate unaided practice and a written exam into the course.
- **Verify facilitator fidelity; keep the model-building phase AI-free.** Pressed to "just tell us" which can weighed more, a purpose-configured Gem invented mass values no one had measured, so a language-based facilitator's fidelity must be checked rather than assumed, and the AI-free build phase preserves the hands-on work it cannot reach (Tufino & Damiani (2026)).

Common Misconceptions

- **"Students trust AI enough to rely on it uncritically."** Fouad and Bentley found a **50-point trust-utility gap**: **91% use AI for coursework but only 41% trust it**. Widespread use coexists with low trust, so an intervention aimed at building enthusiasm addresses the wrong variable.

- **“Physics students are one population.”** Becker et al. developed a two-profile typology from **1,189 survey responses**: **70% “Pragmatic Users” and 30% “Skeptical Non-Users”**. A single classroom policy has to serve two groups with opposite stances.
- **“The gap between use and trust is irrational.”** The two figures measure different things — whether the tool helps you finish work, and whether you believe it does so correctly. Students are distinguishing utility from reliability, which is the analytically correct distinction and not a contradiction.

Chemistry Education

> **Chemistry Education** — the study of how students learn chemistry and how to teach it more effectively, spanning GenAI in laboratory and experimental design, AI-mediated formative assessment, context-based and inquiry-based instruction, the technical accuracy of LLMs on chemistry tasks, and the philosophy of experimentation in the AI age. Chemistry education research engages the discipline's distinctive demands — abstract, submicroscopic concepts, symbolic and representational notation (formulas, SMILES, spectra), and hands-on laboratory practice — which make it a rich and distinctive context for studying how AI both supports and challenges learning.

Questions to Consider

- Chemistry combines abstract submicroscopic concepts, specialized symbolic notation, and hands-on laboratory practice. Before reading, which of these three distinctive demands do you think AI handles well, and which might it struggle with — especially given the page's warning about LLMs failing on rigorous quantitative and spatial-reasoning tasks?
- One study had students design lab manuals with AI, implement them hands-on, and have them validated by professionals — significantly boosting experimental confidence and critical thinking while shifting staff roles from demonstration toward guidance. What makes this 'AI for experimental design' different from just asking AI for answers?
- Systematic evidence shows LLMs can define basic chemistry terms but perform poorly on rigorous quantitative tasks, struggle with spatial reasoning (like NMR), and show overconfidence. If an AI confidently gives you a wrong answer on a hard chemistry problem, how would you detect it — and what skill does that detection require?
- Research proposes assigning AI distinct roles by achievement level — a Patient tutor for low-achievers, a Personal Coach for mid-level, and an Intellectual Sparring Partner for high-achievers. Why do you think the same AI tool should play different roles for different students, and what does that require of the human instructor?
- The page warns of 'epistemic drift' — reliance on opaque algorithms detaching scientific inquiry from causal understanding. If AI predicts an experimental outcome, when does that prediction help you understand chemistry, and when does it quietly replace the understanding itself?

Introduction

Chemistry education has become a fertile domain for AI-in-education research because chemistry combines **abstract conceptual content**, **specialized symbolic representation**, and **physical laboratory practice**. AI tools (notably ChatGPT and conversational agents) are used to explain complex topics, support laboratory work and experimental design, provide personalized Feedback and formative assessment, and simulate experiments. At the same time, research documents LLMs **technical limits** on rigorous chemistry tasks and the risk of **epistemic drift** and over-reliance.

Key research themes

AI-supported laboratory and experimental design is a distinctive strength of chemistry-education research. **Yim & Lui** integrated AI chatbots into an upper-division undergraduate analytical chemistry lab: students used AI to **design lab manuals**, implemented them hands-on, and had them validated by certification professionals — significantly enhancing experimental confidence and Critical Thinking/ Problem Solving skills while shifting staff roles from "cookbook" demonstration toward guidance. The philosophy-of-experimentation strand examines how AI reshapes the epistemology, ontology (AI predictions in a "liminal" space), and methodology of chemistry experiments, and warns of **agency shift** and over-reliance.

Context-based and inquiry-based instruction uses AI within structured pedagogies. **Abdikayumova & Madybekova** combined the **7E instructional model** with PhET simulations and ChatGPT tutoring for Grade 10 chemistry, finding significantly higher achievement and engagement than inquiry-only or conventional teaching — demonstrating the synergy of contextualization, structured inquiry, and adaptive AI. This connects to Constructivism and Personalized Learning frameworks.

AI-mediated formative assessment and human–AI collaboration. Ratniyom et al. found pre-service science teachers perceive distinct, achievement-based roles: the human instructor as an adaptive expert (Simplifier/Elaborator), and ChatGPT as a personalized self-regulated-learning tool shifting from *Patient tutor* (low-achievers) to *Personal Coach* (medium) to *Intellectual Sparring Partner* (high) — proposing an **Instructor–AI Synergistic Learning Ecosystem**. This advances Human AI Collaboration, Formative Assessment, and Self-Regulated Learning research.

Technical accuracy and critical AI literacy. Systematic evidence shows LLMs can define basic chemistry terms but perform poorly on rigorous quantitative tasks and struggle with spatial reasoning (e.g., NMR), overconfidence, and notation sensitivity (Erümit & Özdemir Sarıalioğlu; the ChemBench/QCBench findings in the UNESCO perspective). This makes **evaluative engagement with AI output** — interrogating, verifying, and cross-checking against chemical principles — a central learning goal, connecting to AI Literacy, Critical Thinking, and Reducing AI Misuse.

Ethics, policy, and epistemic drift. The UNESCO-guidelines perspective warns of **epistemic drift** — the risk that opaque algorithms pull inquiry away from causal understanding — and calls for a shift from content delivery to **knowledge creation**, critical AI chemical literacy, human-reasoning-prioritizing assessment, and closing the global access gap.

Connections to related concepts

Chemistry education sits within the broader STEM Education domain and shares much with Physics Education (laboratory practice, abstract concepts, problem-solving) while having distinctive connections: to Assessment and Formative Assessment through AI-mediated evaluation; to Simulation and laboratory learning through virtual experiments. The remaining connections run to Teacher Education through pre-service science-teacher research and professional development; to Educational AI Policy and Ethics through the AI Governance of AI in STEM; and to Philosophy of AI in Education through the epistemology/ontology of experimentation. The AI Literacy and Reducing AI Misuse concepts are essential for the responsible-use dimension, and Higher Education and K-12 capture the levels at which chemistry AI research occurs.

Implications for chemistry instructors

- **Leverage AI for experimental design, not just answers.** Yim & Lui show students designing lab manuals with AI and validating them hands-on builds confidence and critical-thinking while shifting staff from demonstration to guidance — a model for lab courses.
- **Demand evaluative engagement with AI output.** Systematic evidence finds LLMs weak on rigorous quantitative chemistry, spatial reasoning (NMR), and overconfident — make interrogating and cross-checking AI against chemical principles an explicit learning goal.
- **Assign distinct, achievement-sensitive AI roles.** Instructor–AI role research finds the human instructor as adaptive expert and ChatGPT as a personalized tool shifting from Patient tutor (low achievers) to Coach to Intellectual Sparring Partner (high achievers) — differentiate support by student level.
- **Combine AI with structured, contextual pedagogy.** 7E + PhET + ChatGPT outperformed inquiry-only and conventional teaching, showing AI works best inside an established instructional model.
- **Be alert to epistemic drift and over-reliance.** Philosophy-of-experimentation research and UNESCO guidance warn that opaque AI can detach inquiry from causal understanding — preserve human-reasoning-prioritizing assessment and student agency.
- **Grade open-ended handwritten work selectively.** In a 296-student handwritten general-chemistry final, a Multimodal AI LLM graded textual answers and chemical-reaction equations reliably but drawing and graphing worse than random (background grids visually distract AI vision); pairing an IRT-based risk filter and deferring graphical items to humans made automation defensible for summative use (Assisting the grading of a handwritten general chemistry exam with artificial intelligence).

Common Misconceptions

“A model that can explain chemistry can therefore do chemistry.” The capabilities come apart in exactly the places a chemistry course tests. Systematic evidence shows LLMs can define basic terms while performing **poorly on rigorous quantitative tasks**, struggling with **spatial reasoning such as NMR interpretation**, and showing **overconfidence** on both. A tutor built on fluent verbal explanation will appear strong precisely where the subject is easiest and fail where it is hardest, while sounding equally assured throughout.

“Fluency of explanation is a reasonable proxy for reliability.” It is a proxy for fluency. The overconfidence finding is the operative one for teaching: a system that states an incorrect spatial or quantitative answer with the same register as a correct one removes the learner’s cue to check, which is why verification has to be built into the task rather than inferred from tone.

“Adding AI to an existing inquiry lesson cannot hurt.” It can, and the comparison that shows a benefit is narrower than it sounds. Abdikayumova and Madybekova combined the **7E instructional model** with PhET simulations *and* ChatGPT tutoring for Grade 10 chemistry and found significantly higher achievement and engagement than inquiry-only or conventional instruction. The treatment is the structured combination — an

instructional model plus simulations plus tutoring — not the chatbot on its own, and a chatbot added to unstructured inquiry is untested by that result.

“Chemistry is a subject where the answer is checkable, so AI errors are harmless.” Checkable answers are how wrong reasoning passes unnoticed: a student who receives a correct value from a model that reasoned badly has no way to detect the deficiency, and the assessment records success. In a quantitative discipline the verifiable endpoint is the weakest available evidence of understanding.

Biology Education

> **Biology Education** — the study of how students learn biology and how to teach it more effectively, spanning AI-assisted laboratory instruction, AI literacy embedded in biology curricula, critical thinking in the AI era, and the use of specialized tools (species identification, bioimaging, predictive modeling) in biological education. Biology's distinctive demands — large bodies of specialized terminology, visual-spatial and systems thinking, hands-on laboratory and fieldwork, and increasingly computational 'omics methods — make it a rich context for examining both the promise and the risks of AI in STEM learning.

Questions to Consider

- Biology makes distinctive demands on learners — specialized terminology, visual-spatial and systems thinking, hands-on lab work. Before reading, how do you think these features change what AI can genuinely help with in biology versus what it might undermine?
- A virtual lab teaching assistant study found human TAs more accurate and effective than ChatGPT, yet students preferred the AI response 40% of the time and could only detect AI output 45% of the time. Why might students prefer a less accurate AI answer — and what does that say about the 'safety net' needed in lab teaching?
- AI has revolutionized biology research (AlphaFold, computational biology) while its adoption in biology education has been cautious, amid concerns about cheating and erosion of critical thinking. Why do you think the same tools that power scientific discovery are treated with such caution in the classroom?
- One study embedded Machine Learning concepts into a high-school biology course and found the biology context actually supported AI learning — evidence for embedding AI literacy in the curriculum rather than making it an add-on. Where in a biology course would AI concepts naturally arise?
- Researchers argue that as AI reshapes biological research, critical thinking — skepticism, contextual understanding, ethical reasoning — must be deliberately cultivated with human oversight. If AI can now identify species, interpret images, and predict outcomes, what intellectual work is left that students must learn to do themselves?

Introduction

Biology education research on AI clusters around a tension: AI has revolutionized biology *research* (AlphaFold, 'omics, computational biology), yet its adoption in biology *education* has been cautious amid concerns about generative-AI cheating, misinformation, and erosion of critical thinking. The knowledge base's biology articles collectively examine how AI tools function as laboratory teaching assistants, how AI literacy can be embedded in biology courses, how critical thinking must be protected in the AI era, and how specialized AI tools support fieldwork and species identification.

Key research themes

AI in the biology laboratory. **Doğru & Faulconer** tested ChatGPT as a **virtual teaching assistant** in an undergraduate biology lab, finding human TAs more accurate and more effective, though students preferred the AI response 40% of the time and detected AI output only 45% of the time — highlighting both the burden-lifting potential and the safety-need for a "safety net" against incorrect lab information. This parallels the chemistry strand's AI-supported experimental design and philosophy of experimentation — shared concern for AI in hands-on science labs.

AI literacy embedded in biology curricula. **Zha et al.** integrated machine-learning and neural-network concepts into a high-school honors biology course, finding significant gains in AI knowledge and that biology context supported AI learning — evidence for embedding AI literacy in STEM Education rather than relegating it to extracurriculars. **Elizondo-García et al.** used ChatGPT within **challenge-based learning** in biology and math courses, finding students valued immediacy but worried about veracity, teacher replacement, and skill erosion — calling for updated academic-integrity codes and AI-use ethics.

Critical thinking in the AI era. **Papaneophytou & Nicolaou** argue that as AI shapes biological research, **critical thinking** — skepticism, contextual understanding, and ethical reasoning — must be deliberately cultivated, with human oversight remaining indispensable to validate AI outputs and prevent bias. This connects to the knowledge base-wide Reducing AI Misuse and Cognitive Offloading concerns.

Socratic AI argumentation practice in teacher preparation. A quasi-experiment with 124 prospective biology teachers found a ChatGPT-4 Socratic tutor on socio-scientific issues raised argumentation quality over offline peer discussion (adjusted 3.91 vs. 3.21, $F(1,121) = 14.23$, $p < .001$), with the largest gains in rebuttal and counter-evidence skills (Ergasheva et al., 2026).

Specialized AI tools and the broader review. **Cotton & Cotton** review the full landscape of AI tools in biological education, including **iNaturalist and Google Lens** for species identification, bioimaging and machine-learning tools, assistive technologies, and predictive modeling of at-risk students — alongside the integrity, assessment-design, misinformation, and critical-thinking challenges of generative AI. - **LLMs answer better than they mark.** Across 1,344 answers to 336 open-ended biological-statistics questions spanning Bloom's levels, Nguyen et al. (2026) found three models rated above a 20-student group, yet a single Large Language Models (LLMs) marker agreed with an experienced instructor so poorly that no student reached fair agreement.

How much of the grade is actually exposed. Weighting each graded category of one department's 38 core-course syllabi by instructor-rated vulnerability put 33% of course points at high exposure and 81% at least somewhat exposed - 41% and 100% online - with only in-person proctored exams rated minimally vulnerable (Chan et al., 2026).

Connections to related concepts

Biology education sits within the broader STEM Education domain and shares the laboratory-practice and specialized-terminology concerns of Chemistry Education and Physics Education. Distinctive connections: to Critical Thinking through the AI-era emphasis on skepticism and oversight; to AI Literacy through embedding AI concepts in biology courses; to Human AI Collaboration through virtual lab assistants and challenge-based learning; to Academic Integrity and Ethics through generative-AI misuse and policy; and to

Assessment through AI-mediated evaluation. The Higher Education and K-12 concepts capture the levels at which biology AI research occurs, and Intelligent Tutoring and Simulation connect to AI-assisted lab and teaching support.

Implications for biology instructors

- **Keep a human "safety net" around AI lab assistants.** Doğru & Faulconer find human TAs more accurate and effective than ChatGPT, yet students preferred AI 40% of the time and detected AI output only 45% — verify and annotate AI lab information, and never rely on it unmoderated for safety-critical content.
- **Embed AI literacy in the biology curriculum, not as an add-on.** Zha et al. show biology context supports AI learning; integrate ML/neural-network concepts into coursework where they naturally arise.
- **Deliberately cultivate critical thinking in the AI era.** Papaneophytou & Nicolaou argue skepticism, contextual understanding, and ethical reasoning must be taught explicitly, with human oversight to validate AI outputs and prevent bias.
- **Teach responsible use alongside challenge-based learning.** CBL studies find students value immediacy but worry about veracity and skill erosion — update academic-integrity codes and AI-use ethics in parallel with adoption.
- **Survey the specialized tool landscape.** Cotton & Cotton map tools (iNaturalist, Google Lens, bioimaging, at-risk prediction) that instructors can deploy for fieldwork, species ID, and student support — choose purpose-built tools over general chatbots where they fit.

Common Misconceptions

- **"Students cannot tell AI from a human teaching assistant."** A virtual lab teaching assistant study found **human TAs more accurate and effective than ChatGPT**, yet students **preferred the AI response 40% of the time** and could only **detect AI output 45% of the time**. Detection was close to a coin flip and preference ran toward the less accurate source, so satisfaction data cannot stand in for quality here.
- **"Preference indicates quality."** The same study separates them directly: the preferred output was the worse one. Any evaluation of a biology AI tool that reports student satisfaction without an accuracy measure is reporting the wrong quantity.
- **"AI literacy must be taught as a separate subject."** Embedding machine-learning concepts **into a high-school biology course** found the biology context **supported** AI learning — evidence for embedding AI literacy in the curriculum rather than bolting on a standalone unit. The discipline gave the concepts something to attach to.

CS Education

> **CS Education** — computer science education is the most-researched STEM subfield in the knowledge base, benefiting from natural alignment between AI tools and programming tasks. Code generation, debugging assistance, and automated code review are its primary AI applications. Because students learn to build the very tools they use, CS education sits at the center of debates about AI literacy, curriculum redesign, agentic software engineering, and the boundary between genuine learning and over-reliance.

Questions to Consider

- If AI can now write code that passes real programming exams, what should students still learn to do by hand — and what should the curriculum stop teaching?
- Research found that higher trust in an AI coding assistant predicted WORSE ability to tell correct from misleading suggestions. How is trust different from appropriate reliance, and how would you teach the latter?
- In student-AI co-programming, nearly 80% of interactions relied on non-learning strategies like outsourcing answers, and only about 1 in 9 showed deep epistemic engagement. Why does genuine learning rarely happen by default when AI is available?
- A Learning by Teaching agent that was too competent undermined students' debugging practice. Would you deliberately make an AI tutor fallible — and if so, how?
- As AI automates implementation, curricula are shifting from writing code to verifying and directing AI-generated artifacts. What new competencies does that demand, and what might get lost in the shift?
- Students are building the very tools they use. How does being both builder and user of AI change what they should learn about its limits — and its ethics?

Introduction

AI in CS education

- **Code generation and completion:** CS1 code review, DURA for CS2, and NL programming mistakes examine how students use AI for code generation and what they learn from it.
- **Conversational agents for novices (scoping review):** Barzanji & Loitsch (2025) map 23 studies (2019–June 2024) of conversational agents for novice programmers, documenting a shift from rule-based chatbots to Large Language Models (LLMs)- and RAG (Retrieval-Augmented Generation)-based agents (with retrieval-augmented generation reducing hallucination) and personalized tutoring support (e.g., InfoBot, ProbSol-Bot, Lint Bot, Profe Alex). Notably, only 4 of 23 studies ground design in learning theory, and 17 of 23 prototypes are English-only despite most research originating outside English-speaking countries — flagging weak pedagogical grounding and an inclusivity gap for future CA design in introductory programming.

- **Debugging support:** Debugging tools, human-AI debugging collaboration, and dyadic pair-programming modeling leverage AI for error identification and repair.
- **A live course deployment found hint length, not model choice, to be the actionable variable.** Three consecutive deployments in an introductory web development course (o3-mini, GPT-5-mini and GPT-5.5 across 79,438, 83,374 and 10,420 logged submissions) associated hints with better immediate outcomes in several comparisons. Longer messages predicted worse next-submission correctness, more attempts and slower resubmission, and students who had received hints on earlier project steps solved the final step less often, at 95.6% against 98.1% (Mihaylova et al., 2026).
- **A browser-resident tool-augmented tutor is the architecture the field is converging on.** A tool-augmented SLM design pairs a small fine-tuned planner (1B–7B) with four deterministic tools — code executor, test runner, documentation retriever, Knowledge Tracing module — behind a four-tier escalation policy (tools first, on-device SLM, consent-gated cloud LLM, instructor), shifting pedagogical control from the model to the auditable policy; a preliminary ~150M completion model reaches 10.97% HumanEval pass@1, above several 100M–150M code baselines (Suvernev et al. (2026)).
- **A small fine-tuned tutor can out-scaffold a larger general model.** Fine-tuning Qwen2.5-Coder-7B-Instruct on 1,213 synthetic tutoring dialogues cut premature solution disclosure from 7.43% to 1.88% of tutor turns and raised stepwise scaffolding and debugging-question quality above GPT-4o's, though reliable pedagogical plan generation stayed the open problem (Kopytskyi et al. (2026)).
- **Automated assessment:** Linux Bash grading, a large-scale 18-model grading comparison, and LLM intervention review evaluate automated code assessment. The security of that workflow is a separate question: Humble (2026) red-teamed a routine AI grading task and found that instructions hidden inside a submitted file raised a failing essay's grade with no visible warning, in 9 of 9 iterations for one strategy and 17 of 18 for another — evidence that grader robustness belongs on the Assessment Validity checklist alongside accuracy.
- **A one-sentence grader prompt can collapse an LLM, and fine-tuning repairs it.** Habibullah et al. (2026) graded a practical computer vision exam (570 dual-graded students) under 171 configurations and a machine learning exam (1,038 students) under 162 more. A short "strict grader" preamble drove 14 of 17 open-weight models out of the graded band (MAE ≥ 8), with three stopping grading altogether, and the damage traced to two credit-withholding policy sentences whose direction did not transfer to the second exam (seven models improved). One LoRA adapter over roughly 3,900 pooled graded examples brought five small open models to parity with a human grader.
- **AI-generated learning media:** Generated Animated Traces show that AI-generated visualizations can aid immediate learning but must be personalized — mid-engagement students experienced a performance decrement consistent with the expertise-reversal effect.
- **GenAI analogy critique as an instructional asset:** Bernstein & Sibia (2026) ground GenAI analogy reception in CS2: ten students who had already completed CS2 audited GenAI-generated analogies for linked lists and recursion and rejected mappings that failed structural

correspondence — an island-route analogy that mapped to a circular rather than a singly linked list, or a badminton rally offered for recursion despite having no guaranteed shrinking input, with one student proposing golf instead. The work argues that analogy critique is itself a check on concept understanding, making flawed AI analogies a usable instructional asset rather than a hazard to filter out, and recommends assigning them as objects to inspect and repair.

- **Misconception modeling:** a taxonomy of conditionals/loops misconceptions gives automated systems a precise vocabulary for diagnosing novice errors.
- **Model-generated strategic misconceptions:** Miličević et al. (2026) built SocraticTrap-CS around 35 concepts from the ACM/IEEE CS2023 curriculum — algorithms, programming languages, databases, networks and operating systems — and asked seven open-weight models for a fluent, authoritative explanation resting on a subtle error. Six of the seven produced an expert-confirmed strategic misconception for 91% or more of prompted concepts (221 of 241 segments, 91.7%), with no significant differences between CS domains; conceptual errors dominated (66.5% conceptual vs. 33.5% factual, and none purely logical), and both persuasiveness and error type varied by domain. The authors therefore recommend domain-sensitive countermeasures — reasoning-focused checks in programming-heavy courses, cross-referencing against protocol specifications in networking — and evaluation of Automated Question Generation and AI-authored explanations on pedagogical trustworthiness rather than correctness alone.
- **Authentic Assessment performance:** Lepp & Kaimre (2026) show 2026 GenAI systems outscore the average student cohort on authentic introductory OOP assessments and frequently earn full marks on longer programming tasks, yet still struggle with interfaces, abstract classes, inheritance, and image-based questions — recurring error patterns instructors can exploit when designing assessments. A CS1 longitudinal study reinforces the capability side of that finding: Ye et al. (2026) measured frontier models at 98.93-99.99% on the labs against 76.37-88.03% for student submissions.
- **Predictive modeling for at-risk support:** Zhang, Jeffries & Koprinska (2025) show that intrinsically interpretable decision trees trained on content-interaction log features accurately predict module-level progress in large-scale online programming courses (85–91% accuracy across four K-12 courses) and flag “No submission” dropout outcomes, giving educators a 7–8 day window to intervene with struggling and disengaged Learners before module deadlines — complementing the automated-grading and attrition-prediction work above.
- **Retrieval-augmented support for theoretical CS fits asynchronous study only.** AlgoRAG answered all 179 instructor-authored exam questions within a 240-second timeout at a mean 38.0 seconds each, and its BLEU-4 of 0.0000 across the set is a property of n-gram matching on mathematical proofs rather than a system failure (Adhikari (2026)).
- **Adoption tracks the assignment, not the subfield.** Across seven assignments and 211 students, Nizamani et al. (2026) measured LLM use from 89.6% in algorithms to 15.2% in software engineering, attributing the spread to assignment complexity, verifiability and scaffolding rather than to the subject itself.
- **Feedback can be staged so the diagnosis stays hidden.** Riazi & Rooshenas (2026) separate an artifact-grounded diagnosis of a student’s database schema from the workflow that releases it,

with educators authoring the stages; across 383 episodes, 71.1% of feedback reached its target level.

Programming pedagogy: from blocks to embodied, game-based learning

Programming education spans introductory block-based programming to advanced software development, and increasingly grounds abstract code in concrete, observable outcomes.

- **Block-based visual programming:** environments like Scratch and Blockly let beginners snap together graphical blocks rather than type text, eliminating syntax errors and making program structure visible — especially valuable for younger learners and for controlling educational robots. In the AI era they are increasingly combined with conversational AI agents (e.g., Micro:bit + MakeCode in teacher training, small-language-model tutors).
- **Embodied block programming:** RoboBlockly Studio combines block-based programming with a conversational AI teaching agent and embodied robot execution, creating an iterative authoring–running–observing–revising loop that preserves learner Learner Agency.
- **Natural-language robot control:** EduSim-LLM lets beginners control simulated robots through natural-language instructions, lowering the barrier to robot programming without requiring low-level code expertise.
- **Robotics and computational thinking:** Valls i Pou links computational thinking to educational robotics in secondary STEAM curricula, and teacher-training research argues robotics and ML activities should be embedded in Teacher Education.
- **Game-based and gamified learning:** A systematic review compares game-based learning (suited to informal settings) and gamification (suited to formal classrooms) in robotics education, which emphasizes introductory programming and modular kits.
- **Project-based robotics:** Bots and Blocks teaches robotics programming through an agile, semester-spanning project, addressing the theory-practice gap in higher-ed.
- **LLM impact on learning outcomes:** Jošt et al. (2024) and a meta-analysis of GenAI and programming learning examine whether AI-assisted tools help or undermine programming achievement.

Curriculum transformation in the AI era

The question “what should students still learn by hand?” now reshapes computing programs.

- **From implementation to verification:** Reshaping Undergraduate CS Education argues that as GenAI automates implementation-level programming, debugging, and testing, curricula must shift toward *understanding and verifying AI-generated artifacts*, preserving system design, abstraction, and critical evaluation while de-emphasizing low-level implementation details. This aligns with AI Literacy frameworks that prize evaluation over generation.
- **Agentic software engineering as a discipline:** ASE-26 formalizes directing agents rather than writing code — teaching auditability, context engineering, verification, multi-agent workflows, and AgentOps — and positions agentic AI competence as a structured, scaffolded curriculum rather than syntax mastery.

- **From production to judgment: comprehension debt and AASEE.** Mahmoud (2026) argues the field should shift from a production-centered to a judgment-centered model, and extends comprehension debt — the deferred learning and maintenance cost when AI-assisted production outpaces a learner's ability to explain, test, modify, and justify the software — into an Assessment lens, grounded in 621 reflective diaries from 207 students. The review refines the AASEE framework into five non-linear integration levels crossed by four evidence obligations — explain, verify, modify, and account — and reports a conditional evidence base: a STEM meta-analysis with extreme heterogeneity ($I^2 = 96.32\%$) loses its pooled benefit once publication bias is corrected, and syntheses of 76, 72, and 64 studies show short-term efficiency gains that do not transfer to unaided performance.
- **New pedagogies and assessment models:** Test-Driven AI-Assisted Learning replaces lectures with self-directed AI-assisted study gated by weekly closed-book tests, preserving individual accountability while AI agents scale material production and marking under human oversight.
- **Oral examinations as the accountability mechanism.** A project-based AI Engineering program ran second-semester students through seven two-week sprints with AI embedded in requirements, architecture, coding and testing, and made individual oral examinations mandatory after three runs showed artifacts alone no longer evidenced understanding; average missing ECTS fell from 25% to 3% (Rausch (2026)).
- **Teach the model's mechanics offline.** A practitioner resource suite teaches the full LLM training → generation pipeline unplugged — hand-tallied n-gram grids and dice-based sampling, no programming or mathematics assumed — and reports delivery to roughly 400 participants, with engagement beginning only at the generation stage (Swift (2026)).
- **What predicts Vibe Coding success — and what to keep teaching:** A preregistered CHI 2026 study (N=100) of pure "no-code" vibe-coding found that both computer-science achievement ($r = .39$) and written-communication proficiency ($r = .29$) independently predicted performance, with CS achievement remaining significant even after controlling for domain-general cognitive ability and contributing roughly twice the unique variance of writing skill. Because the environment hid generated code, CS knowledge could only help indirectly (problem decomposition, algorithmic thinking) — making the CS estimate a *lower bound* for AI-assisted workflows that also permit editing. The authors argue curricula should weigh written communication alongside CS fundamentals, rather than treating vibe coding as syntax mastery made obsolete.

AI literacy, agency, and the risk of over-reliance

Because programming is where AI assistance is most powerful, it is also where the failure modes are most visible.

- **Trust ≠ appropriate reliance:** Trust and reliance on AI (Pitts et al.) find that higher trust in an AI assistant predicted *worse* discrimination between correct and misleading suggestions during Python Problem Solving — moderated by AI Literacy and need for cognition. Calibration, not confidence, is the goal.

- **Epistemic AI literacy:** Wu (2026) shows that in student-AI co-programming, 78.8% of interactions relied on non-mastery-oriented aims and unreliable strategies (outsourcing, verification-seeking), with only 11.1% showing high epistemic engagement — genuine learning rarely emerges without deliberate design support.
- **AI inquiries are narrow and generation-patterned.** Classifying 830 CS2 prompts against the Graesser taxonomy, Amoozadeh and Alipour (2026) found assertion, verification, and instrumental prompts dominated both sessions, and that first-generation students asked fewer questions and leaned on verification while continuing-generation peers used the AI as an active problem-solving partner.
- **Structural interventions against copy-paste over-reliance:** Soft barriers for copying in AI-assisted programming evaluate lightweight design interventions (e.g., mechanisms that discourage blind copy-paste of AI output) and find they can reduce over-reliance without blocking AI assistance — evidence that the over-reliance risk in CS education is amenable to instructional-design fixes, not just learner-education or bans.
- **Teachable agents and productive practice:** Learning-by-teaching with ChatGPT improved knowledge gains and code quality but undermined error-correction practice because the agent is too competent — a design lesson: make agents *deliberately fallible* so debugging is preserved.
- **Assistance governance:** a scoping review of 90 systems introduces the **PEA framework** (Policy, Enforcement, Authority) for bounding and controlling LLM assistance — a comparative vocabulary for designing Scaffolding that limits over-reliance.
- **Governance fit, not strictness.** Dickey (2026) proposes a six-dimension governance profile — pedagogical grounding, AI instructional authority, human accountability, learner agency, context boundaries, and evaluation visibility — and shows across seven in-house tools and four published programming systems that the same model can distribute authority and accountability very differently; what predicts responsible scale is governance *fit* to the instructional function, not how strict the tool is.
- **Behavioral context for adaptive AI tutoring:** Barron et al. (2026) present **TutorTrace**, a dataset and pipeline that makes learners' behavioral context computable in real time from IDE telemetry in AI-assisted Python courses (N=480). It derives a taxonomy of activity before, between, and across AI queries, and can classify whether an upcoming query reflects guided or dependent Help-Seeking (AUROC=.717) and predict imminent queries (AUROC=.726); behavior-aware prompts reduced no-independent-work query intervals from 50.0% to 20.7% in a preliminary evaluation. This shows how behavioral telemetry can make AI programming tutors adaptive to learners' actual effort, not just their explicit requests.
- **The duality of building what you use:** CS students' unique position creates both meta-cognitive awareness of AI limitations and real risk of Over-Reliance on AI-generated code. Code review interviews and critical engagement studies address this tension directly.
- **Agentic coding and comprehension in team PBL:** Tanaka et al. (2026) introduced Spec-Driven Development with AI agents into an undergraduate software-engineering project course and found that implementation throughput (added LOC) rose across 2022-2025 while heavy AI use

coincided with code-comprehension dips that only recovered after one-on-one instructor checks - direct evidence that throughput gains do not guarantee understanding, and that over-reliance in AI-assisted coding is amenable to instructional monitoring.

- **Continuance, not adoption, is where GenAI's value is decided.** A PRISMA review of 45 studies (2023–2025) finds improved code generation and debugging alongside unchanged conceptual depth, and argues that continued use depends on calibrated Trust, verification skill, and institutional guidance rather than perceived usefulness (Yalwa et al., 2026).

Equity, culture, and who gets into computing

- **Broadening participation:** SuaCode documents motivations for smartphone-based coding among African students (fewer than 1% of secondary-school leavers have fundamental coding skills), informing accessible AI-supported MOOCs for low-resource contexts.
- **Neurodivergence and collaboration:** Neurodivergent computing students report discomfort with ambiguous collaboration structures; structured assignments, smaller consistent teams, and explicit roles improve Accessibility — design lessons for the AI tools entering computing classrooms.
- **Culture shapes perceived ethics:** Canadian vs. South Korean computing students judged identical AI-assisted coding practices differently despite functionally identical policies — policy harmonization does not produce perception harmonization, an Academic Integrity and Equity concern.
- **Collaboration transparency:** Graf et al. find that partners' misaligned beliefs about each other's AI use predict lower project scores, especially for lower-performing students — transparency mechanisms (disclosures, shared logs) may be needed in collaborative programming.

Ethics education and the workforce

- **Ethics-to-behavior gap:** the "Cost-of-Ethics Crisis" shows CS students, despite contemporary ethics education, prioritize compensation, location, and culture over ethical concerns in job searches — a critical gap in how ethics instruction transfers to behavior.
- **Workforce reshaping:** a systematic review of U.S. gray literature frames the "Dual Train Problem" — rapid AI change racing institutional adaptation — and urges durable AI competencies, ethics/governance, and skill-based credentials aligned with emerging roles (e.g., Prompt Engineering, AI auditing, AI policy).

Connections

CS education connects to Computational Thinking, STEM Education, Automated Grading, Prompt Engineering, AI Literacy, Agentic AI, Curriculum Design, Human AI Collaboration, Higher Education, K-12, and Workplace Learning. Its closest applied neighbour is Information Technology Education: CS education takes the program and the algorithm as its object, whereas IT education takes the deployed organizational system and the practitioner's judgment about it — which is why the two fields debate different AI harms, whether code generation erodes programming skill against whether AI troubleshooting erodes diagnostic skill, and ask different questions of their graduates, whether they can build a system

against whether they can govern the systems they administer. It is the domain where AIED tools are both used and built, making it a testbed for Intelligent Tutoring, Robots in Education, Collaborative Learning, Game-Based Learning, and the risks of Over-Reliance.

A 72-study synthesis and the VIE framework. Kumar, Wongsirichot and Nanthaamornphong (2026) reviewed the empirical literature on generative AI in computing and programming education (January 2022 – April 2026, 72 studies, 33 venues) and foreground exactly the structural feature that makes the discipline distinctive: the AI generates the assessable artifact itself, so using the tool, learning the skill and being assessed collapse into one keystroke. Their synthesis of 14 themes finds the field's most replicated effect — short-term efficiency and completion gains (36 studies) — is also its most misleading: those gains do not transfer to unaided performance (21 studies), and prior knowledge moderates whether assistance becomes durable skill or a crutch. Detection research is thin (3 studies) while course redesign is comparatively well evidenced (25 studies), and the review consolidates the corpus into three interdependent design requirements — Verification, Implementation and Equity — where critical engagement with AI output must be a graded, observable component of student work rather than an aspiration left to student discretion (Scaffolding, Assessment Validity).

Implications for computing instructors

- **Design assessments AI cannot coast through.** Exploit GenAI's recurring failure patterns (interfaces, abstract classes, inheritance, image-based tasks) instead of banning tools outright — GenAI systems still struggle there.
- **Autogradable take-home assignments offered no completion resistance.** Kaltchenko & Tiwana (2026) ran 50 ChatGPT sessions per Qiskit assignment and all 150 artifacts executed and passed the grader, because personalization varied parameters rather than task structure; the remedy is direct assessment of understanding — supervised modification or oral defense.
- **Calibrate trust, don't just build it.** Trust-reliance research shows higher trust predicted *worse* discrimination of misleading AI suggestions; teach verification and critical evaluation, moderated by AI literacy and need for cognition.
- **Keep debugging and productive struggle alive.** Choose tools or deliberately fallible agents (learning-by-teaching) that preserve error-correction practice, and personalize AI-generated media to avoid expertise-reversal effects (expertise-reversal).
- **Govern AI assistance explicitly.** Define policy, enforcement, and authority for LLM support (PEA) rather than leaving boundaries implicit.
- **Shift curricula toward verification and agent direction.** As GenAI automates implementation, teach understanding/verifying AI artifacts (reshape curricula) and structured agentic-software-engineering skills (ASE-26).
- **Structure collaboration for all learners.** Smaller consistent teams, explicit roles, and AI-use transparency support neurodivergent students and fair collaboration, especially where misaligned AI-use beliefs lower project scores.
- **LLM-adaptive explanations of programming errors (2026):** A crowdsourced study (N=103) found LLM-rewritten error messages improve readability, but objective debugging performance

depends on matching explanation style (pragmatic vs contingent) to programmer skill — a scaffolding insight for AI-assisted programming education (Beyond the Traceback: Using LLMs for Adaptive Explanations of Programming Errors).

- **Oversight is about fitness, not correctness (2026):** Coding 962 student-AI turns from 145 first-year software engineering students, Shakiba and Chaffey (2026) found 74.4% of interventions named fitness problems against 16.9% naming correctness, and 51.0% of responses modified the output rather than the prompt.
- **"Agreement on code means the grader reads the code."** The benchmark's two instructor raters agreed at **0.815** on C++ answers: **four** models exceeded them with an interval above 100% of that ceiling and **fourteen** fell below, down to **33%**. On the same code task, a note asking for full marks raised Qwen3 235B's grade by **83.2% of the scale**, and seven models across the battery credited blank answers, so a grading pass over student code needs failure tests beside the agreement number.
- **"The effect is the same at every stage of a course."** It grew with the work: on **60 complete Java programs** graded on a **14-level** rubric, the label's effect was **2.8 times** its short-answer size on GPT-4.1-mini and **2.4 times** on Qwen, though only **0.4 times** on Gemini. Task and rubric are part of what the effect measures, so a size validated on short answers does not transfer to programs.

Common Misconceptions

- **"Students pair-programming with AI are learning to program."** In student-AI co-programming, **nearly 80% of interactions relied on non-learning strategies like outsourcing answers**, and only **about 1 in 9 showed deep epistemic** engagement. The dominant pattern is transacting for output.
- **"Conversational agents for novices are grounded in learning theory." Only 4 of 23 studies ground design in learning theory**, so most of the evidence base documents what a system did without a theory of why it should work.
- **"The tooling literature reflects the field's global distribution." 17 of 23 prototypes are English-only despite most research originating outside** English-speaking contexts. The prototypes serve a narrower population than the research does.

Engineering Education

> **Engineering Education** — the study of how students learn engineering and how to teach it effectively, spanning how AI transforms engineering pedagogy, assessment, faculty development, and the engineering workforce. The engineering education articles in this knowledge base cluster around several themes: the figurative language instructors use to make sense of AI, ethical governance of AI use, embodied and multimodal assessment of conceptual understanding, and how AI is reshaping the engineering and computing workforce.

Questions to Consider

- Engineering is a profession where graduates' decisions affect public safety and infrastructure. If students rely on AI to do design and Problem Solving work, what is at stake that wouldn't matter in a purely academic subject?
- Engineering instructors in the same department often hold fundamentally different mental models of AI — some see it as a social 'agent,' others as a technical 'tool.' How might those divergent framings change what students learn to do with AI depending on which instructor they get?
- Hands-on laboratory and embodied learning have long defined engineering education. If AI can simulate or even automate design tasks, does hands-on experience still matter — or is something genuinely lost when practice becomes simulated?
- One line of research assesses engineering understanding by tracking students' gestures alongside their speech, finding that close gesture–speech coupling signals coherent conceptual understanding. What could a student's hands reveal about understanding that their words alone might hide?
- Research finds ethical guidance about AI in engineering is mostly student-facing and compliance-oriented, with weak reciprocal accountability for faculty and institutions. Whose responsibility should the safe use of AI in engineering really be?

Introduction

Engineering education research is distinctive because it sits at the intersection of professional formation and rigorous STEM content. It emphasizes design, problem-solving, hands-on and laboratory learning, teamwork, and preparing graduates for professional practice. Design is also the ground it shares with Design Education, and the two divide it by what can be checked: engineering's assessed object admits calculable artifacts and carries public-safety accountability, while design education's is the studio process behind the artifact — sketch, iteration, critique — the very evidence generative tools can now produce without the process that once generated it. AI raises distinctive questions here: whether hands-on and embodied experience still matters when AI can simulate or automate design tasks; the professional and ethical stakes of AI use (engineers' decisions affect public safety, infrastructure, and Sustainability); and how AI reshapes the competencies graduates need and the workforce they enter.

How AI appears in the knowledge base's engineering education research

- **Faculty understanding and shared language:** Gerhardt et al. analyze the metaphors engineering instructors use to describe AI, finding that most frame it either as a human-like "social being/agent" or as a "technical tool," and that instructors within the same department often hold fundamentally different mental models. Because metaphors both construct and constrain understanding, they argue a shared, accurate language is essential for Educational Development and departmental discussions about AI.
- **Ethics and responsible use:** Osunbunmi et al. systematically review empirical studies of AI in undergraduate engineering education, identifying seven recurring forms of ethical guidance (transparency, accountability, student independence/agency, privacy, Academic Integrity, fairness/equity/bias, beneficence). They find ethical guidance is predominantly student-facing and compliance-oriented, with reciprocal faculty and institutional accountability underdeveloped — a concern heightened by engineering's direct stake in public safety and societal Well-Being.
- **Embodied and Multimodal AI assessment:** Morphew et al. develop a multimodal framework integrating computer-vision gesture tracking with Large Language Models (LLMs) analysis of speech to assess engineering students' conceptual understanding of statistics, showing that gesture adds diagnostic evidence beyond speech and that close gesture–speech coupling signals coherent understanding.
- **Workforce transformation:** Fletcher et al. review U.S. gray literature on AI and the engineering/computing workforce, framing the "Dual Train Problem" (rapid change vs. urgent policy) and recommending durable AI competencies, Ethics and AI Governance, and skill-based credentials for emerging roles.
- **Student adoption and reliance:** Nguyen et al. extend the Technology Acceptance Model with *critical use* to model how engineering/CS students form intentions to use GenAI and how that intention predicts reliance across understanding, assessment, programming, and engineering-project tasks — finding moderate, appropriate reliance and heavy use for understanding-related tasks but limited use for full assessment writing. Asag & Al Mamun integrate TAM with UTAUT to model Bangladeshi engineering students' adoption, explaining 64% of usage variance and highlighting job relevance, result demonstrability, and subjective norms as key drivers.
- **Prompting strategy predicts performance, not usage volume:** among 128 fourth-year engineering students, AI Query Efficiency and AI-Driven Problem-Solving were the strongest predictors of academic success and remained significant after controlling for cumulative GPA (Isaza Dominguez et al. (2026)).
- **Students' own metaphors exceed what the tools deliver:** Kudina (2026) found 100 engineering students most valued LLMs for writing support, conceptual clarification and coding, yet framed them as "oracle" and "tutor" — authority and personalization a probabilistic text generator cannot supply, a "cruel optimism" that depends on verification skills students are still building.
- **Embed AI in the discipline, not beside it:** a project-based thermal-engineering curriculum folded machine learning into existing thermal topics across introductory, application and advanced levels

rather than adding computer-science courses, and undergraduates meeting only minimal entry requirements produced weaker projects than graduate peers (Li et al. (2026)).

- **AI tutoring and feedback for quantitative engineering courses:** Yin et al. (2026) introduce Arthur, an AI teaching assistant that delivers real-time, personalized feedback on Calculated Formula Questions in an undergraduate Engineering Economics course — a domain where pen-and-paper, unstructured solutions have blocked prior AI support. Its full life-cycle pipeline (curating previously graded handwritten submissions, random-masking data augmentation, per-question XGBoost diagnosis backbones, and a dialogue-based question-bank web interface) offers a scalable pathway for AI feedback across engineering courses that lack structured digital data, and the framework is designed to generalize to CFQs in other engineering disciplines.
- **AI for sustainability, integrated rather than modular.** The four-pillar AI-SEE framework (intelligence-driven, green-empowered, responsibility-leading, practice-integrated) distributes AI across engineering coursework; in a 144-student transportation-engineering case, students reported engagement across personal, academic, professional, and social levels, with sustainability reasoning carried into families and peer networks (Liu et al. (2026)).
- **A tool-rich studio can depress efficacy without improving the product.** In a 27-student architectural design studio, teams using a generative-AI plus XR pipeline showed larger pre–post declines in design Self-Efficacy ($\beta = -1.675$) and outcome expectancy ($\beta = -2.088$) than controls, while one headset per student produced no coordinated collaboration (Xiao et al., 2026).
- **Model choice, not prompting, sets feedback reliability under pushback.** Apostolakis et al. (2026) built 200 verified two-dimensional truss problems and put thirteen models through three postures: solve, confirm a correct solution the student insists is wrong, and locate an injected error. Solving accuracy ran from 64.5% to 97.0% and every model caught at least 90.4% of injected errors, so neither separated the field; resistance to pushback did, ranging from 46.5% to 98.5%. For a statics course the tutoring risk is not a wrong final answer but a model that agrees when a student wrongly doubts correct work, and the authors note that if reliability tracks paid tiers, the feedback students receive will vary with what their institution can license.

Signature concerns

Engineering education's signature concerns shape how AI is taken up: **hands-on and laboratory learning** (and what is lost when AI simulates practice), **professional formation** (ethical responsibility, safety, and societal impact), **design and problem-solving** (how much cognitive work AI should do), and **competency-based preparation for the workforce**. These make engineering education a rich site for studying whether AI augments or displaces the cognitive work essential to professional expertise — paralleling debates in Physics Education, Math Education, and CS Education.

Connections to related concepts

Engineering education sits within STEM Education and connects strongly to CS Education (computing and software engineering), Math Education and Physics Education (engineering's mathematical and physical foundations), Workplace Learning and Educational Development (workforce and instructor preparation),

Assessment and Ethics (the professional and evaluative stakes of AI), and Higher Education (the institutional context). It is the home discipline for the knowledge base's ASEE-sourced articles.

Under-covered sub-areas

The knowledge base's engineering education coverage is still developing. Sub-areas that would benefit from further articles include **discipline-specific engineering pedagogies** (mechanical, civil, chemical, electrical, software, and bioengineering education), **design and maker education**, **capstone and project-based learning**, and **engineering ethics education** — where AI's role is likely to be especially consequential.

That gap is no longer empty in one area: a three-year biomedical engineering program ran generative AI as a guarded knowledge-summarization and coding scaffold inside a four-module PBL sequence — approved tools, no patient data, disclosure logs — and reported A-rates of 66.4% against 39.1% for pre-AI cohorts (Nnamdi et al. (2026)).

Implications for engineering instructors

- **Build a shared, accurate language about AI.** Faculty metaphor research finds instructors hold fundamentally different mental models (agent vs. tool); align departmental understanding before making policy.
- **Close the ethics-to-accountability gap.** Ethics reviews find guidance is mostly student-facing and compliance-oriented; strengthen reciprocal faculty and institutional accountability, given engineering's stake in public safety.
- **Use multimodal, embodied assessment.** Gesture + speech assessment adds diagnostic evidence beyond language alone — consider embodied cues when evaluating conceptual understanding.
- **Prepare students for the workforce, not just the course.** The Dual Train Problem urges durable AI competencies, ethics/governance, and skill-based credentials aligned with emerging roles.
- **Model critical use and appropriate reliance.** Critical-use TAM research shows students rely on AI heavily for understanding tasks but less for assessment — guide them toward appropriate, verifiable reliance across task types.
- **Teach AI use as a skill inside class time.** Geng et al. (2026) ran nine instructor-led demonstrations, each 10–15 minutes at the end of a lecture and sequenced from tool literacy through strategic delegation to model evaluation — but students seeing no connection to assessment reported them redundant, so tie them to graded work.

Common Misconceptions

- **"AI adoption among engineering students is a technology-acceptance problem."** Asag and Al Mamun integrate TAM with UTAUT to model Bangladeshi engineering students' adoption, **explaining 64% of** the variance — so a substantial share sits outside the acceptance constructs, in social and cognitive factors the model does not cover.

- **“Students use AI for what it is best at.”** Kudina (2026) found **100 engineering students** most valued LLMs for **writing support**, not for engineering reasoning. Their metaphors for the tool exceeded what it delivered, and their actual use followed convenience rather than capability.
- **“A richer tool stack improves design outcomes.”** In a **27-student** architectural design studio, teams using a generative-AI plus XR pipeline showed **depressed efficacy without an improved product**. Tool richness can cost confidence while leaving the artifact unchanged.

STEM Education

> **STEM Education** — science, technology, engineering, and mathematics education is the most common domain for AI in education research in the knowledge base. STEM's structured knowledge, clear right/wrong answers, and computational nature make it an ideal testbed for AI tutoring and assessment.

Questions to Consider

- STEM is the most common domain for AI-in-education research because its knowledge is structured and has clear right/wrong answers. Do you think that makes STEM the easiest place to teach with AI — or possibly the place where AI's limits are most easily masked?
- The page cites research showing AI adoption in schools is 'stratified by discipline' — normalized in computer science, heavily prohibited in mathematics. Why do you think subject culture shapes AI acceptance so strongly, and what are the consequences for students?
- If a math student uses AI mainly to check solutions and get explanations, is that a scaffold or a crutch? What determines the difference, and where would you draw the line?
- Given that STEM problems often have verifiable answers, what kinds of AI use in STEM do you think genuinely build understanding versus merely produce correct-looking output?
- How might the very qualities that make STEM ideal for AI tutoring — clear answers, computable correctness — undersell the parts of science and engineering that are messy, open-ended, and judgment-based?

Introduction

STEM as the primary AIED domain

- **Mathematics:** Math education research spans GenAI impact on math learning, elementary fraction tutoring, and competence clustering.
- **Mathematics ITS evidence is bounded and conditional.** A structured narrative review of 20 publications (2020–April 2026) found the clearest measured advantage for real-time diagnostic Feedback layered onto the same adaptive system, yet concluded that intelligent tutoring supports mathematics learning only when valid learner modeling, calibrated scaffolding and teacher mediation combine, and that scalability is technical, not educational (Ogunsakin et al. (2026)).
- **Physics:** Physics education includes ChatGPT typology studies, Socratic physics chatbots, and scoring bias analysis.
- **Computer science:** CS education is the most-researched STEM subfield — code review, debugging tools, and prompting studies.
- **Engineering:** Engineering scaffolds, mechanics demonstrations, and curriculum balancing bring AI to engineering education.

- **Scaffolding undergraduate research:** An and colleagues (2026) pilot an AI system that converts research publications into structured, comparable datasets for undergraduate thesis completion across four STEM schools. Results (20 students, 80 documents) showed >90% extraction of experimental parameters, ~65% reduction in literature-review time, and a 50% increase in students' ability to identify influential experimental variables — evidence of how AI-scaffolded undergraduate research can strengthen research literacy and epistemic cognition in STEM education.
- **Simulation-supported instruction:** In drone-based STEM education, teacher-AI co-designed Simulation scaffolds were evaluated against an identical hands-on curriculum with 30 secondary students, testing whether simulation-supported instruction yields superior learning outcomes. GenAI's role was to accelerate content creation while teacher involvement preserved pedagogical validity and contextual relevance.
- **Outcomes favored the scaffolded group.** The simulation group outgained the hands-on group on curriculum-aligned STEM knowledge (M = 3.00 versus 2.06; t(28) = 2.23, p = .034, d = 0.82) and on 21st-century competencies (d = 1.52) (Yeung et al. (2026)).
- **Digital twins in STEM: prototypes outrun measured learning.** A PRISMA review of 11 higher-education studies found every one demonstrated a working, hardware-synchronized prototype, yet only three (27.3%) reported statistically significant learning gains, with development complexity and reduced social interaction the recurring barriers (Pelayo-González et al., 2026).
- **AI-assisted planning in STEAM arts education:** An experimental study of children's STEAM arts teachers (Luo and Tahir 2025) found ChatGPT-assisted lesson plans outperformed teacher-generated ones on expert-rated quality (median 20.5 vs. 17.6, p = .002, large effect, six professor raters), with teachers reporting gains in efficiency and interdisciplinary integration (61% rated 4+). The result came through the teacher's delegation method — most usefully by having ChatGPT fill content gaps in a self-outlined lesson — reinforcing the recurring point that AI lifts STEM/STEAM work when the teacher structures the task and critically evaluates output rather than handing the whole plan to the model.

How effective AI-supported instruction is in STEM, pooled

The largest quantitative synthesis for this domain to date — 35 experimental and quasi-experimental studies published between 2005 and 2025 (Doğan, Kılıç, Kalınkara and Talan, 2026) — puts AI-supported instruction in STEM at Hedges' g = 0.670 (95% CI [0.491, 0.848]), with the between-study variance handled by a random-effects model. The level breakdown is the informative part: effects were largest in high school (g = 1.099) and progressively smaller in university (0.578), elementary (0.465) and middle school (0.392). By contrast, the subject-area differences that STEM's self-image would predict — science (0.676) and mathematics (0.650) ahead of technology and engineering (0.501) — were not statistically significant (Q = 4.85, df = 2, p = 0.088). Duration did not behave as a dose: the strongest band was one to two months (g = 0.833), the shortest interventions of five hours or less still reached 0.621, and the weakest band (g = 0.256) was not significant. Read alongside the skepticism documented on Learning Gains, the reasonable reading is that AI-supported STEM instruction produces a moderate, real but level-dependent effect, not a uniform one.

A subject-area review of 18 studies (2014–2024) sharpens what those effects are measured on: AI's outcomes in science and chemistry education concentrated on learning-process measures (n = 9) rather than

achievement, and the evidence base skews to teacher candidates (44.4%), with only one middle-school and two high-school studies (Erümit and Özdemir Sarıalioğlu (2025)).

Why STEM dominates

STEM's structured knowledge representation, verifiable answers, and computational thinking alignment make it the most natural fit for AI tutoring. Computational thinking research explores this alignment explicitly.

New evidence from 2025–26 IJ STEM Education research

A concentrated batch of 2026 *International Journal of STEM Education* studies sharpens how AI functions across STEM's subfields and levels:

- **Subject-specific AI Governance shapes student AI use.** A cross-sectional study of 416 Czech secondary students (Navigating AI in STEM: what secondary students actually do with generative AI-driven tools) found AI adoption is *stratified by discipline* rather than unified: computer science and economics normalize GenAI as a collaborative resource, while mathematics (65.9% prohibit) and natural sciences (55.3%) show high perceived prohibition co-occurring with poor rule clarity and persistent clandestine use. Students mostly use AI as an instrumental scaffold (explanation, solution-checking) rather than a substitute, but a critical evaluation gap emerges — heavy prompt modification overshadows external factual verification, shifting behavior toward Cognitive Offloading. This argues for *subject-sensitive* guidance over blanket bans.
- **AI as a co-inquirer in inquiry-based STEM.** A quasi-experiment with 97 third-graders (Inquiry-based learning in STEM education: the impact of generative AI-based chatbots on primary school students' problem posing ability in science) showed GenAI chatbots significantly outperformed search engines for science problem posing in inquiry-based learning, improving question quality, producing a more integrated epistemic network structure (ENA), and lowering cognitive load. A systematic review of ChatGPT for inquiry-based learning in STEAM (The AI-powered co-inquirer: a systematic review of ChatGPT for inquiry-based learning in STEAM education, 24 studies) confirms ChatGPT supports question formulation, inquiry design, Problem Solving, and reflection — but risks over-reliance, hallucination, and superficial conclusions when outputs are treated as authoritative.
- **STEAM is an uneven pathway to AI literacy.** A PRISMA systematic review of 39 studies (STEAM education for AI literacy: a systematic literature review) found STEAM implementations chiefly develop technical literacies (fundamental AI concepts, computational thinking, data literacy) while underdeveloping ethical awareness, creative imagination, creating/managing/designing with AI. Technology disciplines lead; arts, engineering, and integrated STEAM lag — indicating AI literacy in STEM is currently lopsided toward technical skill over responsible shaping of AI.
- **Adaptive AI-based STEM programs can support deep learning.** A cluster-randomized pilot in sixth-grade science (Developing deep learning in science through an adaptive AI-based STEM instructional program: evidence from sixth-grade classrooms, N = 30) found an adaptive AI-based

STEM program (personalized content, rule-based mastery, real-time feedback) produced large effect sizes favoring the experimental group across explanation, interpretation, application, and idea generation — though the two-classroom design warrants cautious interpretation.

- **Teacher acceptance is heterogeneous and discipline-shaped.** A latent profile analysis of 128 pre-service teachers (Unpacking the heterogeneity of pre-service teachers' ChatGPT acceptance: a latent profile analysis across STEM and non-STEM disciplines) found four ChatGPT-acceptance profiles (Pragmatic Evaluators, Technology Pioneers, Resistant Skeptics, Environmental Observers), with STEM teachers concentrated in Technology Pioneers and non-STEM teachers in resistant profiles — and Resistant Skeptics showing high ease of use but low intention, demanding differentiated AI Literacy training.
- **Teaching students to interrogate the model, not just to use it.** A single 45-minute session on prompting and error-checking raised undergraduate physics posttest scores (d = 0.814) and leveled the advantage of prior AI experience (Huang et al., 2026).
- **Assessment and cognitive processes in AI-integrated STEM.** The CTAT (34-item, IRT-validated) provides a valid instrument for assessing Computational Thinking within AI-training contexts, revealing students struggle most with data representation, logical-operator sequencing, and loop structures. A grounded-theory study of AI-assisted programming (Tool, tutor, or crutch?: a grounded theory of cognitive scaffolding and offloading in AI-assisted programming education) shows learners oscillate between "Domain Mastery" and "Tool Mastery" through Scaffolding and Offloading loops, with attenuated metacognitive calibration under routine offloading — a process-level account of the performance-learning tension.

Implications for STEM instructors

- **Choose discipline-appropriate AI.** STEM spans math (tutoring), physics (Socratic dialogue, Simulation), CS (code generation, review), and engineering (design, workforce) — select tools matched to each subfield's signature Pedagogies and Teaching Strategies rather than assuming one general chatbot fits all.
- **Use AI's structured-fit advantage, but protect reasoning.** STEM's verifiable answers make it the most AI-tractable domain; guard against over-reliance and answer-replacement by embedding AI in structured, mastery-oriented workflows.
- **Embed AI literacy across STEM courses.** Studies (biology, math teacher prep) show STEM context supports AI learning — integrate AI concepts where they naturally arise rather than isolating them.
- **Watch equity and access in AI adoption.** STEM AI tools are not neutral; monitor scoring bias, Digital Divide access, and culturally relevant design as you deploy them.

Common Misconceptions

- **"Intelligent tutoring works across STEM uniformly."** A structured narrative review of **20 publications (2020-April 2026)** found the clearest measured advantage for **real-time diagnostic**

tutoring specifically. The evidence is **bounded and conditional**, and generalising it to all mathematics ITS overstates what was reviewed.

- **“Simulation is a pale substitute for hands-on work.”** The simulation group **outgained the hands-on group on curriculum-aligned STEM knowledge (M = 3.00 versus 2.06; t(28) = 2.23, p = .034, d = 0.82)**. The simulation was not a fallback performing below the real thing.
- **“An AI-assisted literature workflow mainly saves time.”** Results from **20 students across 80 documents** showed **over 90% extraction of experimental parameters, roughly 65% reduction in literature-review time, and a 50% increase in students’ ability to identify influential** work. The capability gain was the larger result and the time saving was the smaller one.

Science Education

> **Science education** — the study and practice of how students learn science and how to teach it, now being reshaped by generative AI (LLMs, simulations, virtual labs, and AI grading) across physics, chemistry, and biology. The science-education articles in this knowledge base reveal a field negotiating a core tension: AI demonstrably supports inquiry, misconception correction, and assessment at scale, yet its value depends on instructional design, and it carries real risks of over-reliance, hallucination, and dehumanized, profit-driven learning.

Questions to Consider

- The page opens with a tension: AI demonstrably supports inquiry and misconception correction at scale, yet its value depends entirely on instructional design. Before you read, when has a tool you used in science teaching seemed powerful yet pedagogically hollow — and what made the difference?
- An AI-facilitated physics inquiry 'invented' mass values that no one had measured when students pressured it. What does this incident reveal about treating AI outputs as authoritative in science, and how should students be trained to treat a confident-sounding answer?
- Research suggests AI may currently add more value as a scalable content generator than as an interactive tutor — in one study, well-crafted conceptual-change texts (expert or AI-made) beat a prompted AI dialogue. Does that surprise you, and what does it suggest about where the real pedagogical payoff of AI in science lies right now?
- AI graded 10,364 handwritten physics assessments with high agreement with human graders, yet multimodal models still show gaps on complex reasoning and diagram generation. What is it about 'authentic, representation-heavy' science work that might resist automated assessment?
- Physics students show a striking trust–utility gap — high use, low trust — and split into pragmatic users and skeptical nonusers. If students themselves are domain-calibrated skeptics, what does that imply for one-size-fits-all policies about AI in science classrooms?
- A critical voice warns of 'AI colonization' of science education — extraction without consent, algorithmic monoculture, dehumanized reform. Before you read, where do you think the benefits of AI in science education are being oversold, and what would a human-centered, justice-oriented alternative look like?

Introduction

Science education is where AI's promise and its limits collide most visibly, because the disciplines demand rigorous Multimodal AI reasoning — visual-spatial thinking in physics, laboratory skills in chemistry, and organism-level systems in biology — alongside well-structured, verifiable content that LLMs handle well. The thirteen articles synthesized here span all three disciplines and levels, from K-12 secondary classrooms to Higher Education university courses and pre-service teacher programs. Across them, a consistent picture emerges: AI functions best not as an answer generator but as an embedded partner — a co-inquirer, a content

generator, a virtual lab assistant — whose contribution is decided by instructional design and the surrounding pedagogical structure.

A four-week randomized evaluation of an AI revision platform in GCSE science gives the picture a causal estimate — Hedges' g = 0.33, with no evidence the effect differed by subject or disadvantage — against an already technology-rich counterfactual, so the figure is added value rather than AI versus nothing (Harrison et al. (2026)).

Structured access, not access itself, drives the gain: team-reported growth averaged 17% under unlimited individual access but 34% and 31% when access was structured, which also preserved more peer discussion (Malikova et al., 2026).

These classroom-level findings sit inside a larger methodological question. Martin, Rost, Koenen and Graulich (2026) argue that science education research may currently be amid an epistemic iteration, drawing on Hasok Chang's (2004) account of successive stages of knowledge that build iteratively toward specific epistemic aims. In their reading, AI methodologies may transform not only how the field analyzes student learning but which epistemic aims, criteria and practices it prioritizes. They propose a seven-phase reflective framework (problem framing; instrumentation and measurement; experimentation and evidence-based inference; comparisons and replication; building norms and consensus; implementation and its consequences; and continuous refinement), illustrated by the roughly 150-year development of thermometry, and present it as a reflective instrument rather than a validated method or an empirical finding.

Virtual labs and simulations

AI is dramatically lowering the barrier to creating customized, embodied science instrumentation. Levy et al. show that a four-element natural-language prompt can generate a hand-controlled augmented-reality physics simulation (a pinch-and-spread gesture tunes a virtual lamp's wavelength), with 86% of pilot students reporting greater engagement. Similarly, Suñer et al. generated a browser-based rotation laboratory entirely through prompting, validated against video analysis to better than 1%. These works reframe generative AI as a programming tool that lets teachers design software around pedagogical intent rather than adapting activities to fixed apps — advancing embodied and Simulation-based learning. In Chemistry Education, Abdikayumova & Madybekova embedded PhET simulations and ChatGPT tutoring within a context-based 7E inquiry cycle for Grade 10 students, achieving significantly higher achievement and engagement than either component alone — evidence that contextualization, structured inquiry, and adaptive AI act synergistically. Behavioral analysis of how learners work inside such modeling environments reinforces this design lesson: tracing 315 online learners building ecological models in VERA, An, Hammock & Goel (2025) found that learners who engage in full-cycle, hypothesis-driven exploration build the most complex and diverse models, whereas observation-heavy learners largely copy existing models — suggesting scientific modeling tools should actively promote full-cycle exploratory behavior rather than leave learners in a passive, observation-dominated mode.

AI tutors and inquiry-based learning

Inquiry-based learning is a central theme. Jiang et al.'s systematic review of 24 studies positions ChatGPT as an "AI-powered co-inquirer" used mainly in the conceptualization, investigation, and discussion phases of STEAM inquiry, improving performance, critical thinking, and engagement — yet risks over-reliance,

hallucination, and superficial conclusions when outputs are treated as authoritative. Aydın found that eight weeks of AI-supported guided inquiry produced large gains in pre-service teachers' conceptual understanding of photosynthesis and respiration, while AI literacy and computational thinking showed no significant change — suggesting disciplinary learning can improve even when broader competencies need longer or more explicit instruction. Tufino & Damiani show AI can scaffold the epistemic core of ISLE inquiry while remaining confined to the verbal channel, but found facilitation fragile: under student pressure, the AI "invented" mass values that no one had measured, underscoring Hallucination Risk and the need to verify rather than assume AI fidelity. Kuhn et al. propose the AIRIS framework (Activate–Inquire–Reflect) to keep prediction, interpretation, and evaluation non-delegable human tasks, and call for "withdrawal condition" experiments testing whether learning survives AI's removal — a direct response to the "boiling frog problem" of eroding epistemic practice. Expert judgment of AI-generated lesson plans extends this design lesson to curriculum-aligned science: Karaismailoglu, Surmeli and Yildirim (2026) had eleven Turkish science-education specialists score ChatGPT-4 and an education-focused tool (Teacher's Buddy) on sixth-grade plans for a "Sustainable Living and Biodiversity" unit aligned to the Engineering Design-Based Learning (EDBL) model. Both platforms scored highest on "Presenting the solution" yet lowest on Engineering Skills (general-purpose $\bar{x} = 37.45$; education-focused $\bar{x} = 41.45$) — a shared weakness in simulating the iterative, process-oriented stages (prototyping, failure analysis, revision, reflective retesting) that define design-based learning — and only 3 of 11 experts judged either plan directly "Applicable," with 7 rating them "Can be applied by correction."

Isolating AI's contribution in a three-group climate socio-scientific study, students whose structured inquiry included an AI partner outgained inquiry-only peers on decision-making ($d = 0.69$), with the largest gains on monitoring and adaptive management while data collection improved equally across conditions (Gousopoulos (2026)).

A conceptual review grounds the material channel theoretically: science is an open system that revises claims against physical evidence, while a language model is operationally closed to evidence at inference (Muminova & Mamatkulov, 2026).

Misconceptions and conceptual change

On conceptual change, the evidence is nuanced and partly counterintuitive. Akdoğan found in a 413-student Solomon Four-Group design that both expert-written and AI-generated conceptual change texts were equally and significantly more effective at reducing heat-and-temperature Misconceptions about AI than interactive AI dialogue, which offered no advantage over control — positioning AI's current pedagogical value as a scalable content generator rather than an interactive tutor, with gains concentrated among high-achieving students (an equity concern). This is reinforced by Borse et al., who show that prompt specificity shapes physics-solution quality and that MAPS-guided critique better prepares students to evaluate AI output than independent problem solving, treating AI fallibility as a Critical Thinking learning resource.

AI grading and assessment

AI grading is advancing rapidly on high-stakes work. Pathak et al. graded 10,364 scanned pages of handwritten physics assessments (including a national Olympiad and team-selection camp), achieving high score correlations (0.91–0.97) and recovering the same five-student team as human grading — arguing AI

works as a valid second reader and audit tool under examiner control when given detailed, physics-specific rubrics. Short-answer auto-marking has a longer and more foundational transformer lineage: Morley et al.'s scoping review of 21 studies (2017–early 2024) found BERT-family models dominated auto-marking of short-answer science questions through 2021 before GPT-based approaches were adopted via prompting from ~2022, that models augmented with domain data (textbooks, rubrics, further pre-training) consistently outperformed baselines, and that unresolved threats to reliability, explainability, and fairness argue for such auto-markers as supports to, rather than replacements for, human examiners. Yet Chen et al.'s OmniPhys Benchmark reveals that multimodal LLMs still show significant gaps on complex reasoning and diagram *generation*, cautioning against over-trusting automated physics assessment on the authentic, representation-heavy tasks that define deep disciplinary competence. A chemistry counterpart sharpens the format-dependence: Cvengros & Kortemeyer graded a 296-student handwritten general-chemistry final with a multimodal Large Language Models (LLMs), finding high agreement with TAs for textual and chemical-reaction answers but *worse-than-random* performance on drawing and graphing (background grids distract AI vision) — evidence that reliable AI grading in science is selective by response format and requires confidence-based deferral to human examiners for graphical items, rather than a uniform "grade everything" approach.

Teacher perceptions and the critical view

Teacher readiness is decisive. Amponsah et al. found Ghanaian pre-service science teachers hold positive attitudes and strong intentions toward AI but only moderate actual classroom use — an intention–use gap pointing to Teacher AI Competency and institutional support as the real levers. Becker et al. and Fouad & Bentley document that physics students are domain-calibrated skeptics, not uncritical adopters: a 50-point trust-utility gap (91% use, 41% trust) and two distinct user profiles (Pragmatic Users vs. Skeptical Non-Users) that challenge one-size-fits-all policies. Counterbalancing the techno-optimism, Avraamidou warns of an "AI colonization" of science education — extraction without consent, algorithmic monoculture, and dehumanized, profit-centered reform — and calls for a feminist, human-centered AI prioritizing justice over profit, while Erümit & Özdemir Sarıalioğlu's systematic review of 18 studies emphasizes ethical risks (bias, hallucination, plagiarism, erosion of independent thinking) and the need for teacher training and conscious use. The collective lesson across all thirteen articles is that AI in science education delivers gains when embedded in sound inquiry, Scaffolding, and Assessment design — and undercuts learning when it displaces the epistemic work students must do themselves.

General AI comfort did not transfer to the discipline's own tools. Among 100 geography students at one Kazakh university, readiness to teach with AI and GIS tracked GIS familiarity ($\rho = 0.508$) and GeoAI knowledge ($\rho = 0.425$) but not general AI familiarity ($\rho = 0.071$, $p = 0.485$) — a lesson for teacher preparation in any tool-shaped discipline (Laiskhanov et al. (2026)). Sixty-seven percent called themselves ready in some form, yet only 6% had used the combination in practice and 43% judged available instruction adequate. The evaluation is self-reported and unvalidated, so it describes what these students say about themselves.

Schroeder et al. (2026) ask how well general models handle the science content itself: on NGSS-aligned item sets for middle school (1,078 items) and high school (1,150 items), nine open-weight models mostly exceeded 90%, with model size unrelated to accuracy. A science teacher judged 236 of 240 sampled items (98.3%) aligned while flagging the absence of diagrams, data interpretation, and mathematical representation

— text-only items cannot exercise every NGSS performance expectation. The high item difficulty and low discrimination leave open whether the items need improvement or secondary science has become tractable for this class of models, and the authors call multi-turn, evidence-based feedback the missing standard.

In a 42-study meta-analysis of GenAI and motivation, the smallest subject-domain effect was in science ($g = 0.109$, 95% CI [−0.107, 0.325], $k = 3$), the only domain whose interval crossed zero, so the pooled evidence does not support a motivational case for GenAI specifically in science (Fang et al. (2026)).

As a framework rather than a study, Zhai et al. (2026) reframe the target: Vision I science literacy for competence in science careers, Vision II for science in everyday and civic life, and Vision III for knowledge and action at community and societal scale. They argue that generative AI earns its place in science classrooms only when it makes curriculum, instruction and assessment cohere with one of those visions, and that the field's persistent problem is tests that reward terminology recall while standards ask for explanation and investigation.

Common Misconceptions

- **"AI in science education has no causal evidence."** A **four-week randomized evaluation** of an AI revision platform in GCSE science gives a causal estimate of **Hedges' g = 0.33**, with **no evidence the effect differed by subject**. The effect is modest and it is causal.
- **"Give students access and the gains follow." Structured access, not access itself, drives the gain**: team-reported growth averaged **17% under unlimited individual access but 34% and 31% when access was structured**. The structure was the intervention.
- **"Scientific simulation requires specialised software."** A **four-element natural-language prompt** can generate a **hand-controlled augmented-reality physics simulation**. The barrier to authoring a simulation fell to the prompt design, which shifts the skill required from programming to specifying the phenomenon.

Writing

> **Writing** — the use of AI tools for writing instruction, Assessment, Feedback, and the study of how generative AI reshapes the writing process itself. Writing education is one of the most AI-affected domains, because LLMs excel at the very activities writing instruction centers on — text generation, revision, and evaluation. Research in this area spans automated scoring, AI feedback quality, writing-process support, second-language writing, academic integrity, and the deeper question of how AI changes what it means to write and to be a writer.

Questions to Consider

- The page's central claim is that writing is not merely output but a cognitive, social, and rhetorical process — and that AI can displace the very mental work that makes writing a learning activity. When you write, what happens in your thinking that a finished AI-produced paragraph simply erases?
- A common framing is 'AI as a tool' or, at the opposite extreme, 'AI as a threat to authorship.' The page offers a third view: writing as a human-AI entanglement where agency is distributed. Which of these framings matches your own experience of writing with or without AI — and what does each framing imply for how you'd teach?
- Research found that delegating *deeper* layers of writing — reasoning and argumentative logic — harms your independent writing more than delegating surface layers like grammar. Think about your last AI-assisted piece of writing. Which layer did you actually delegate, and what does that predict about what you can now do on your own?
- The page warns that AI writing feedback is not language-neutral: personalizing feedback with a student's race, language, or disability can shift it in stereotype-aligned ways — such as overpraising or withholding critique. If you've received or given 'personalized' AI feedback, how would you detect that a tool was softening its critique for some learners?
- The design guidance here is 'coaching, not composing' — have AI ask questions and critique outlines, but require the learner to produce prose first. Why might letting the learner draft before the AI intervenes protect ownership and judgment in ways a tool that writes the draft could not?
- One finding: students often say 'it's OK because…' to rationalize AI use, moving the issue from plagiarism policing toward ethics and AI literacy. If you were designing a writing course, how would you build honesty and ethical judgment about AI into it, rather than relying on detection or punishment?

Introduction

Writing is not merely output but a cognitive, social, and rhetorical process. This is why AI's impact on writing education is so consequential and contested: AI can be a scaffold that helps students draft, revise, and receive feedback they otherwise wouldn't get, but it can also displace the cognitive work — and the human audience — that make writing a learning activity. The knowledge base's research consistently frames AI in

writing as a *human-centered complement* to, rather than a replacement for, the social and cognitive processes of writing. Where the focus is **English specifically** — English for Academic Purposes (EAP) and English language teaching (EFL/ESL/L2) — see the dedicated English Education (EAP / EFL / ESL) concept page, which distinguishes English-specific and academic-register research from general writing and general language learning.

How AI in writing education appears in the research

- **Automated essay scoring:** Automated Essay Scoring systems like anchor-based AES and AIAWE evaluate student writing at scale, raising questions about construct validity and the reduction of writing to measurable features. For short argumentative writing (about 150–200 words) in Spanish, AI scoring agreement varies sharply by rubric dimension (Curi et al., 2026): structure- and register-oriented items — introduction, conclusion, register, nominal agreement, subject–verb agreement — reached moderate chance-corrected agreement with human raters in the 2025 edition, while micro-level linguistic items (vocabulary, syntax, punctuation, connectors, argumentation) stayed in the fair-to-slight range. This suggests LLM assistance is most defensible for macro-level discourse features, and that low-level language conventions should keep deterministic tooling or human review.
- **A quality-dependent tilt.** Out-of-the-box GPT and Llama graders agreed weakly with human raters (QWK 0.17–0.28 versus 0.72 between two humans), overscoring short, underdeveloped essays and underscoring longer, stronger ones for minor surface errors (Mathew et al. (2026)).
- **Score more samples, not bigger models.** In a Grades 3–6 universal-screening study, LLM comparative-judgment scores converged with researcher rubrics (r = .59–.73) and averaging the three screening waves raised criterion validity (β = .68–.74 for ELA scale, AUC = .82–.86 for proficiency), while greater model capability or cost added little (Mercer & Reed (2026)).

Agreement is a property of the corpus, not the scorer: Li (2026) scored 60 student marketing posts with deterministic rules, an LLM and an equal-weight hybrid — the LLM led at ICC(2,1) = .435 while the hybrid's .266 retained the rules' negative bias — and adding 15 low-quality anchors lifted the LLM to .846.

- **Writing feedback:** AI feedback quality research (GenAI vs. teacher feedback, care-full feedback, repeated AI feedback) examines whether AI feedback improves writing and how it compares to human feedback. The PAIRR model (Peer and AI Review + Reflection) combines AI with Peer Assessment and finds AI feedback is most useful in a human-centered process. An 8-week quasi-experiment with 61 Chinese L2 writers (Tang et al., 2026) gives that human-centered claim a concrete shape: teacher feedback delivered far more items (316 versus 185 in the first task) and re-prioritized toward organization and argumentation, but its posted-revision advantage gave way from 4.06 to 2.73 points once a second task demanded structural change, while AI-assisted peer feedback held a narrower, steadier focus and edged ahead (3.89 points, with a task-2 revision mean of 89.82 against the control's 88.35 — a small difference that did not reach significance). Neither mode moved syntactic complexity, so the authors argue for a hybrid "AI-Peer-Teacher" division of labor: AI for error marking and content guidance, peers for negotiating revisions, teachers for complex syntax and argumentation.

- **Pairing AI with peer feedback raises engagement and writing scores.** In a 10-week Chinese EFL course, adding ChatGPT feedback before peer review lifted behavioral, affective and cognitive engagement (partial η2 of 0.28 to 0.32) and improved all four IELTS writing dimensions, most on task achievement (d = 1.41) and lexical resource (d = 1.28) (Liu (2026)).
- **AI feedback does not adapt to writing stages the way teachers do.** Almousa et al. (2026) found the teacher changed significantly on five feedback focus types between draft stages — Praise rising from 26.9% initially to 84.9% in final drafts — while the closest model moved on three types and the smallest on none, and no model reproduced the teacher's differentiation of higher- and lower-performing students.
- **Revision and dialogic positioning:** Where most writing-feedback research asks whether a revision improved the text, Zhao and Ji (2026) ask what stance the revised text takes. Coding 168 EFL argumentative essays with Appraisal Theory — first drafts, revisions after peer feedback, and ChatGPT-4 revisions of the same drafts — they found the three conditions statistically indistinguishable in how much Engagement language they used, but differently configured: peer-feedback revisions became more contractive (more Counter and Endorse, less Entertain), while the AI revisions kept a more balanced Contract/Expand mix that combined stronger counter-claiming with continued hedging. Their reading is that an AI revision is most useful as a contrast text students compare against their own revision rather than as a model answer, and that AI feedback on argumentation can improve prose while quietly closing down the writer's dialogic space — a dimension no current rubric captures.
- **Writing process support and agency:** Agency gap research and stage-ownership research explore how AI changes the writing process from planning to revision, and how students' Learner Agency is affected when AI participates at different stages.
- **Posthumanist perspectives:** A posthumanist approach to AI literacy reframes writing as a human-AI entanglement in which Learner Agency is distributed, challenging both uncritical anthropomorphization of AI and its dismissal as a mere tool — a relational rather than transactional view of AI literacy.
- **L2 / multilingual writing:** L2 writing assessment, linguistic diversity research, and stage-ownership research address how AI supports (or constrains) second-language and multilingual writers, including the risk of reinforcing Standard Academic English norms. The knowledge base's youngest L2 sample comes from a nine-week GenAI-supported opinion-writing program with 301 Grade 5 and 6 students in Eastern China (Lu et al., 2026), which raised ideal L2 writing self and academic buoyancy and improved rubric-scored language use while leaving organization and total scores unchanged — AI support moved specific dimensions of writing rather than writing ability as a whole.
- **Bias in personalized feedback (Marked Pedagogies):** Tan et al. (2026) show that Large Language Models (LLMs) writing-feedback tools are not language-neutral: personalizing feedback with a student's race, ethnicity, ELL designation, learning disability, achievement, or motivation systematically shifts feedback in stereotype-aligned ways — including positive feedback bias and feedback withholding bias (overuse of praise, less substantive critique, assumptions of limited ability) for students marked by race, language, or disability, even when the

essay is identical. This makes "personalization" itself a bias vector that writing-feedback tools must audit and control.

- **Academic integrity:** Survey evidence complicates the policing frame directly: among 504 sociology students (Kuznetsov et al., 2026), 65 percent had used GenAI for coursework but only 3 percent to generate assignment text and 2 percent to produce a full draft, while fear of an academic offense was the second most common concern (28 percent) and roughly a quarter reported no guidance at all (19 percent) or guidance they found unclear. On this evidence the writing-education problem is ambiguity about permitted use, not widespread text generation. Nash and Burriss (2026) show how such ambiguity is produced at the classroom level. Coding 27 preservice English language arts teachers' own classroom AI policies, they found that 26 of 27 permitted some generative AI use but overwhelmingly on teacher-specified terms, with 22 of 27 allowing AI for ideation and brainstorming while disallowing AI composition of sentences, paragraphs or papers. Limits were rarely operationalized — one participant allowed AI "to get your thinking started" and declared "this is where the line should be drawn" without saying where — and many policies simultaneously prohibited submitting AI text and held students responsible for the AI text they submitted, a contradiction that leaves students unable to comply. Twenty-two of the 27 policies were silent on reading altogether, ceding AI-supported comprehension work to no guidance at all.
- **The boundary moves with the assignment, not the tool.** Across 192 practice records, editing was Responsible in 21 of 22, while drafting was Responsible in 11, Contested in 9 and Problematic in 13, so the assessed capability rather than the tool sets the category (Tie, Gil Ortega and Zhao (2026)). Just four studies defined a boundary, designed an intervention around it and tested whether decisions aligned.
- **Policy diverges across five sites.** Interviewing 20 undergraduates, Kim and colleagues locate five distinct sites of AI policy — faculty intention, formal policy, student interpretation, self-policy, and practice — and catalogue 23 rationalizations, mostly ad hoc and post hoc, explaining why rules at one site rarely shape behavior at another (Kim et al. (2026)).
- **Grading is where the guidance runs out.** In interviews with 24 university writing professors across the Chinese Mainland, Hong Kong, Macau and Singapore, six reported no institutional rule on whether they may grade student work with AI at all, and the consequence was colleagues who refuse on principle sitting beside colleagues who already do it (Wu and Lam (2026)).
- **Compliance can mask absent inquiry (academic erasure).** From 49 educator accounts, Nwagboso & Atuba (2026) name *academic erasure* — fluency that satisfies every surface criterion while bypassing the epistemic labor of argument — and trace its driver to assessment culture, where rubrics rewarding polish make AI use the rational response rather than misconduct.

Writing as thinking

Because writing is a cognitive process, AI-in-writing research connects to Cognitive Offloading (does AI writing support bypass thinking?), Metacognition (does AI feedback improve Self-Assessment?), Self-Regulated Learning (do students regulate their use of AI feedback?), and AI Literacy (can students evaluate AI-generated writing critically?). The critical-thinking scaffolding and AI feedback for critical thinking

research show that the pedagogical value of AI in writing depends on whether it prompts reflection and judgment rather than answer-replacement.

Essay authorship tracked prompt volume in a synthesis task — 80% of the text written by the learner in the minimal-prompting cluster against 2% in the heaviest — while connective density correlated negatively with prior knowledge rather than prompt count ($r = -.30$, $p = 0.007$; Poquet et al., 2026).

A two-wave validation with Chinese EFL learners (EFA N = 305; CFA N = 342) separates six regulatory dimensions and adds *environmental regulation* — checking generated content, filtering suggested resources, and limiting reliance — a facet existing L2 writing scales had not carried (Wang, Zhang and Zhang (2026)).

Chen (2026) sharpens this with a **layer-sensitive** account of cognitive offloading in GenAI-assisted academic writing: delegating *deeper* layers (reasoning, argumentative logic) carries a stronger negative association with independent no-AI writing quality and higher-order thinking than delegating surface layers (grammar, vocabulary). Open AI collaboration yielded the best supported product but the worst independent outcomes, while bounded support with reflection preserved competence — evidence that GenAI writing support is not uniformly harmful but its effect depends on which cognitive layer students delegate.

- **Gating AI output on prior engagement moves effort back to the writer.** With 398 participants, Su et al. (2026) found writers composed for 28.02 minutes against 23.26 with an open chatbot, then evaluated passages faster (17.41 vs 22.21 minutes) at equal accuracy and no extra task time. Where Chen locates the cost in *which layer* is delegated, this design decides *when* the model may speak at all.

Lu et al. (2027) extend this thinking to *multimodal* composing by younger writers. Having 60 Grade 5 students externalize their narratives as AI-generated images and short videos produced sustained self-reported gains in interpretation, analysis, evaluation, and explanation — the facets multimodal resemiotisation exercises — but **no gain in inference**. Making meaning visually explicit lowered the demand to infer implicit meaning from text, exactly the offloading mechanism Chen describes; only structured peer discussion restored occasions for inference. The study cautions that multimodal AI composing helps young writers reflect on clarity and coherence while potentially skimming off the inferential work that text-only writing preserves — a design consideration for writing instructors pairing AI visuals with peer feedback.

A dimension-specific pattern recurs across this literature, and it is a useful diagnostic. In the primary-level L2 writing program, emotional and behavioral engagement rose while cognitive and metacognitive engagement did not, and the authors name diminished self-monitoring during writing as an explicit risk of GenAI support (Lu et al., 2026). Enjoyment and on-task activity are therefore not evidence that deeper processing is happening — the same distinction the offloading research draws when it asks which layer of cognitive work a student has delegated.

A 2026 meta-analysis (Teng, 2026) of 11 study-level effects drawn from 31 studies reinforces the diagnosis from the opposite direction. It reports a large average advantage for GenAI-supported writing instruction ($g = 0.80$) but heterogeneity high enough that a new implementation could plausibly show no benefit at all, and the only robust moderator was risk-of-bias classification rather than any pedagogical feature — study quality, not teaching design, explained most of the variance. The same synthesis finds GenAI consistently stronger on lower-order features (grammar, lexical diversity, sentence fluency) while higher-order effects on

argumentation and coherence remain inconsistent, which is precisely the layer gap this page treats as the central design problem.

Designing AI writing support: coaching, not composing

Because writing has no single correct answer, AI writing tools require a different design from answer-verifiable tutors. The knowledge base's design guidance (see the worked **AI writing coach** example in the FAQ on Designing an AI Tutor) centers on preserving authorship and evaluative judgment rather than producing finished text:

- **Track writing capabilities, not just essay scores.** A writing coach's learner model can track argument (thesis specificity, claim–evidence alignment, counterargument), organization, evidence integration, revision, and style — so feedback targets capabilities that persist across essays.
- **Ground feedback in the assignment.** Retrieve the actual prompt, rubric, course readings, citation and genre conventions, and AI-use policy so feedback references the specific assignment rather than inventing generic expectations.
- **Treat writing stages differently.** AI involvement at planning reduces perceived ownership less than at drafting, and AI-generated drafting produces the largest ownership decrease. So a coach can ask questions and critique outlines at planning while requiring the learner to produce prose first at drafting.
- **Make feedback prioritized and reflective.** Each round can offer one strength to preserve, one high-impact issue, one question requiring the writer's judgment, and one concrete revision goal — and the coach should ask learners to evaluate whether they agree with a suggestion, developing evaluative judgment rather than obedience.
- **Preserve authorial voice and guard against homogenization.** The coach should distinguish errors, clarity issues, rhetorical choices, and style preferences — and not automatically "correct" the latter, especially for multilingual writers and non-standard rhetorical styles.
- **Teach the process, not only the tool.** A five-week process–genre unit that built planning, genre analysis and revision around AI-supported multimodal writing raised all three outcomes in a 32-student seventh-grade quasi-experiment (informative text r = 0.66; multimodal r = 0.84; AI-assisted writing r = 0.86) (Günay and Özden, 2026).

Two recent syntheses qualify how well this design guidance is followed in practice. A review of 23 empirical customization studies (Luo, 2026) finds that although goals have moved toward writing processes and higher-order skills, the dominant technical route remains prompt engineering (13 of 23 studies) aimed at optimizing output quality, with learning theory confined to the interface so the system behaves "largely theory-agnostic" — a mismatch that helps explain the overreliance and superficial revision the same studies report. Its reframing is to treat customization as architecture rather than wording: sequencing stages, withholding answers, and building in revision loops. A structured five-part workflow tested over 11 weeks with 53 Saudi EFL undergraduates (Alshehri et al., 2026) shows the alternative in practice — students frame problems and design prompts, draft, revise, verify claims and citations against scholarly databases, and regulate their own reliance, logging what they accept or reject and why. Writing proficiency and digital critical thinking rose together in that condition (15.23 versus 11.91 and 89.84 versus 56.18 at posttest) while

the no-AI control barely moved, though the single-site, partly self-reported result is a preliminary upper bound rather than an established effect.

Screening 51 second-language studies of GenAI feedback found that writing-quality measures were often unrelated to the feedback the model had been asked for, and that pairing AI with teacher feedback beat either source alone (Crosthwaite & Sun (2026)). The same corpus is overwhelmingly English, at 46 of the 51 studies, with Chinese and Arabic the dominant learner first languages.

This coaching-not-composing stance is the writing-domain expression of the knowledge base's overarching "coach over crutch" boundary: identify the cognitive activity that produces learning (planning, drafting, evaluating, revising) and design the AI to support it without taking it away from the learner.

Connections

Writing education connects to Automated Essay Scoring, AI Feedback Quality, Academic Integrity, Cognitive Offloading, AI Literacy, Language Learning, Formative Assessment, Peer Assessment, Metacognition, Self-Regulated Learning, and Higher Education. It is a domain where AI's capabilities and risks are both highly visible, making it a rich site for studying how AI transforms pedagogy, Assessment, and the very nature of authorship and Learner Agency.

What GenAI demands of the task

Al Nafjan (2026) proposes the Rigor–Commitment Alignment Framework (RCAF), which locates engagement in the writing task and the teaching around it rather than in the tool (Rigor, commitment, and generative AI: a conceptual framework for student engagement in EAP writing). Academic rigor is the demand a task places on sustained cognitive effort and disciplinary reasoning, and the framework splits it into cognitive demand, epistemic authenticity, and performance accountability. Teacher commitment is defined narrowly, as commitment to students' learning enacted through instructional responsiveness, relational support, and critical scaffolding, not as a trait a teacher has or lacks. The author is explicit that the RCAF is propositional and has not been empirically validated, so it is a design vocabulary for writing programs rather than a tested effect.

For task design the claim is that rigor and commitment interact rather than add. High demand with thin support is predicted to push students toward concealment and detection games, while warmth without demand lets fluent output pass for learning. Only the high-demand, high-support configuration is predicted to produce deep engagement, with evaluative judgment doing the work of deciding when output is useful, insufficient, or misleading. Because GenAI can produce acceptable academic prose, the framework gives writing assessment a specific obligation: require visible drafting and revision so that performance stays tied to the thinking it is supposed to represent.

Implications for writing instructors

- **Frame AI as a complement, not a replacement, for the writing process.** The knowledge base's research consistently treats AI as a scaffold for drafting, revision, and feedback while protecting the cognitive work and human audience that make writing a learning activity — coaching over crutch.

- **Use AI feedback within a human-centered process.** PAIRR finds AI feedback is most useful combined with peer review and reflection; design feedback loops that keep the instructor and peer audience central.
- **Students want the human at the high-stakes end.** Yildirim-Erbasli et al. (2026) found 81.7 percent of 93 undergraduates preferred human scoring for a final paper worth 40 percent of the grade, trusted AI for grammar and mechanics but not creative writing, and wanted AI scoring reviewed by a human.
- **Audit automated feedback for bias.** Marked Pedagogies shows LLM feedback shifts in stereotype-aligned ways when personalized with student attributes — monitor for positive/withholding bias, and be explicit that personalization can be a bias vector.
- **Guard the cognitive work of writing.** Watch for over-reliance that bypasses planning, revision, and self-assessment; use AI at chosen stages (stage-based ownership) to protect student agency.
- **Design for empowerment rather than enforcement.** A PLS-SEM study of 327 Chinese EFL undergraduates (Li & Zhang, 2026) tested the two levers writing instructors actually hold and found only one of them works. AI prompting literacy strongly predicted perceived competence, psychological safety, and intrinsic motivation, and all three psychological needs partially mediated its link to deep revision engagement, with intrinsic motivation the strongest single driver of deep revision. External mandates had no direct effect at all. The practical translation is that requiring deep revision does not produce it — the enforcing requirement may be needed to make revision happen at all, but the depth comes from building students' prompting capability and the intrinsic motivation and psychological safety that follow from it.
- **Address academic integrity constructively.** Move from policing AI use toward building AI Literacy and ethical-use framing that lets students use AI without unintentional misconduct.
- **Detection is not an integrity strategy for writing.** Bassett et al. (2026) argue detector scores cannot meet the balance-of-probabilities standard integrity cases require and that the human-or-AI dichotomy misreads work created *with* rather than *by* AI, recommending institutions move budget from detection and surveillance toward assessment design and AI Literacy.
- **"Feedback and the grade are independent outputs."** They are not, and the order matters: told a grade that contradicted the work, **all 22** benchmark models wrote feedback whose tone followed the told grade, and for **eight** the shift per point was at least as large as the shift that came with the work's quality. The measure is a word rule validated on tutoring replies, so it reads tone rather than substance. Produce or check the grade before the feedback is written.
- **"Anonymous marking is only a fairness gesture."** It is also an experimental control, and removing it moved marks. Answers graded with a true or swapped attainment label in the prompt differed by **0.28 to 0.75 points** on a ten-point scale on every model tested, and the shift ran through the student description rather than the work (pooled **rho = +0.84**). A grader told the student's record is not marking the essay alone. Withholding learner context is the automated equivalent of anonymous marking.
- **"Asking for a paragraph and asking for an essay are the same kind of help."** Trace data separates them. Across **361 logged messages** from **77** college essay writers, requests that handed

over planning, drafting and revision at once were the largest category: **137** such queries from more than half the participants. Within it, **20** asked for a whole essay, and **15 of the 77 (19.5%)** submitted essays with no typed words of their own. Asking for a paragraph around an idea was the smallest category, at **10** participants. Coding every query against the writing process shows what a finished essay cannot.

The most complete classroom account of that redesign is the PAIRR deployment. Stillman et al. (2026) report 13 sections of 10 writing-intensive courses and 654 students in 2024, spanning developmental writing, first-year composition, professional writing and STEM writing courses. Students read about language models first, then exchanged peer feedback, and only then prompted a chatbot for rubric-driven feedback. The prompt said "Do not rewrite my paper for me." The authors' argument for the sequence is what the course can control: a model positioned as one peripheral voice cannot take over the draft without the instructor's rubric noticing.

Common Misconceptions

"AI writing support is just faster writing." Writing is a cognitive, social and rhetorical process, not merely output, which is why AI can displace the very mental work that makes writing a learning activity. The design guidance that follows is *coaching, not composing*: have the system question and critique outlines while the learner produces the prose. A tool that generates the draft has removed the thinking the assignment existed to develop, however good the draft is.

"Better writing assessment needs a bigger model." It needs more samples. In a Grades 3–6 universal-screening study, LLM comparative-judgment scores converged with researcher rubrics at **r = .59–.73**, and averaging the **three** screening waves raised criterion validity to **β = .68–.74** — an improvement from design rather than scale. Reaching for a larger model when the reliability problem is sampling is the wrong lever.

"AI feedback and peer feedback are substitutes." They combine. In a 10-week Chinese EFL course, adding ChatGPT feedback *before* peer review lifted behavioral, affective and cognitive engagement (partial η^2 of **0.28 to 0.32**) and improved writing scores across the board. The sequencing is doing work — the AI pass readied students for the peer pass rather than replacing it.

"Students act on AI feedback when it is offered." Uptake is selective. Weston and Long (2026) tracked two undergraduate biology teams revising a proposal introduction against instructor-built AI feedback: 10 of 22 comments were addressed, deletions outnumbered additions, and the comments requiring students to judge coherence or claim support were ignored entirely.

"A model can stand in for the teacher's feedback pattern." It has not done so in the evidence. Tracking one teacher across draft stages found significant movement on **five** feedback focus types — with *Praise* rising from **26.9%** in initial drafts to **84.9%** in final ones — while the closest model moved on three and the smallest on none, and no model replicated the pattern. Teacher feedback reallocates emphasis by draft stage; model feedback tends to hold its distribution. Treating the second as equivalent loses the trajectory.

- What Are Best Practices for Writing Instruction in the Context of AI?
- What Are Best Practices for Developing an Effective AI Tutor?

Language Learning

> **Language Learning** — the study of how AI supports second language (L2) acquisition, writing development, and linguistic diversity in educational settings. AI in education research in this knowledge base spans AI interlocutors for spoken dialogue, automated writing evaluation for L2 learners, reading support, and concerns about language bias in AI scoring systems.

Questions to Consider

- Language is inherently interactive, which makes it well-suited to conversational AI — but AI's linguistic capabilities also raise risks of bias against non-native patterns. Where have you seen this tension between opportunity and risk play out?
- One study found AI scoring systematically underestimates linguistically weaker students, while another proposed comparing students to their own prior work rather than native-speaker norms. How does the 'reference point' for evaluation change whether AI feedback helps or penalizes a learner?
- AI interlocutors can extend communicative practice at scale, but the page warns they should pair with human interaction so fluency transfers to real conversation. What might you gain from practicing with an AI that a human partner can't give — and what would you lose?
- Teacher support — not just the AI tool — was shown to drive engagement in AI-assisted language learning through students' achievement goals. How does the social and pedagogical context shape whether learners keep engaging with an AI practice tool?
- A meta-analysis found small-to-moderate, level-dependent gains from emerging tech, with productive skills (speaking, writing) gaining more than receptive ones. Why might speaking and writing benefit more than listening and reading from AI tools?
- If AI privileges standard English and can penalize non-native or diverse language patterns, how should language instructors design evaluation and feedback so AI supports linguistic diversity rather than erasing it?

Introduction

Language learning has emerged as a significant AI in education domain because language is inherently interactive — making it well-suited to conversational AI — and because AI's linguistic capabilities raise both opportunities (personalized language practice at scale) and risks (systematic bias against non-native language patterns). The articles in this knowledge base explore both sides of this equation. Where the target language is **English specifically** — especially English for Academic Purposes (EAP) and EFL/ESL/L2 English teaching — see the dedicated English Education (EAP / EFL / ESL) concept page, which distinguishes English-specific research from general L2 acquisition and general writing.

AI as language tutor and interlocutor is the most developed theme. **What Changes When the Interlocutor Is an AI?** examines interactional fluency and linguistic uptake when L2 learners converse with AI versus humans. **TACT** provides pedagogically adaptive ESL tutoring. **Children's English reading story**

generation via supervised fine-tuning of compact LLMs with controllable difficulty and safety explores AI-generated stories for children's reading development. These connect to Intelligent Tutoring and Generative AI. **Yang, Weng and Yang (2026)** designed two Large Language Models (LLMs)-based agents — a conventional AI English teacher and one using the **5E framework** (engage, explore, explain, elaborate, evaluate) for inquiry-based grammar learning. Across **37 ESL students** in a randomized comparison, **high-performing students responded positively to the AI teacher** while low-performing students showed mixed attitudes, and the conditions differed in intrinsic motivation, cognitive change, and performance — indicating that LLM-agent design should be matched to learner proficiency.

For physically embodied tutors, a meta-analysis of 11 RALL studies (N = 595) found a large pooled effect on L2 learning (g = 0.83) with high heterogeneity, and only interaction format moderated it — group-based formats beat one-on-one while robot morphology, modality, autonomy, and social role did not (Wang, Zhang & Zou (2026)).

AI in language assessment is emerging as LLMs support item generation and evaluation. **Aryadoust and Wong (2026)** compared prompt engineering against fine-tuning for automatic item generation in L2 listening assessment: iterative prompt refinement improved item quality but plateaued, while **fine-tuning GPT-4.1 on the optimized prompt** (holding prompt design constant) yielded further gains — a template for when assessment developers should invest in model adaptation over prompt iteration.

A comparison of 52 EFL assessment tasks rated by 20 experienced teachers found no significant quality difference overall between AI-generated and human-developed items, but a clear division of labor: AI was preferred for grammar and vocabulary (69%) and human development for reading, writing, listening and speaking (75–83%) (Nourashrafi, Alavinia and Darvishi (2026)).

Automated writing evaluation for L2 learners evaluates AI's ability to assess non-native writing. **Bannò et al.** proposed a self-referential approach comparing student writing to their own prior work rather than native-speaker norms. **Feser & Tschisgale** found AI scoring systematically underestimates linguistically weak students — a finding that connects to Assessment Validity and Bias Mitigation concerns. **Generative AI and linguistic diversity in academic writing and publishing: Perspectives from World Englishes** explores how AI affects linguistic diversity in academic contexts.

A discourse-level system goes further by naming the defect rather than scoring the text: sentence-pair relation classification localized coherence breaks - logical jumps, missing connectives, ambiguous reference - and teacher-judged adoption of its generated feedback ran 71.2%-88.4% (Wang et al., 2026).

Accessibility for language learners connects to Inclusive Learning: **DysLexLens** analyzed how dyslexic learners use AI for literacy support, and **AI tools in Arab University English classrooms: Looking back and forward** explored AI tools in Arabic-English classroom contexts. These studies connect language learning to Equity and Special Education.

Motivational mechanisms in AI-assisted language learning examine why learners engage with AI for language practice. **Wang & Wang (2026)** used goal-setting theory with 758 Chinese university English learners to show that **teacher support** enhances engagement in AI-assisted learning through students' mastery-approach and performance-approach goals (not avoidance goals) — evidence that the pedagogical and social context, not just the AI tool, determines whether learners stay engaged with AI-assisted language practice. This connects language learning to Motivation and Student Engagement.

Annamalai et al. (2026) add a qualitative self-determination case: in interviews with 25 Malaysian undergraduates, ChatGPT supported competence and autonomy, and its conversational responsiveness produced a sense of being heard — an "AI-mediated motivational ecology" in which relatedness is partly met by the tool, though inaccurate references demanded verification and human complement.

Design quality, not usage frequency, carried the motivational effect in an instructor-built tutor: across 74 undergraduates using a course-scoped Japanese GPT, out-of-class usage frequency showed no significant correlation with autonomy, competence, or relatedness, while learners rated the tutor highly for self-directed learning (M = 4.39) and cited affective safety (60.8%) (Lee & Kwon, 2026).

GenAI-supported writing at the primary level. Lu et al. (2026) ran a nine-week opinion-writing program with 301 Grade 5 and 6 learners in Eastern China, with eight intact classes randomly assigned to the program or to conventional instruction. The program raised learners' ideal L2 writing self (adjusted mean difference 0.20) and academic buoyancy (0.17), and lifted behavioral and emotional engagement, but it did not move growth mindset, cognitive or metacognitive engagement, or rubric-scored organization — among writing dimensions only language use improved. Two features of the design matter for language teachers: prompting was taught explicitly, through a categorized bank of prompts tied to specific writing goals, and GenAI feedback was used alongside comparison with teacher feedback and repeated revision. The authorship gains learners reported rested on that instructional structure rather than on the tool by itself, and the authors name reduced self-monitoring and shortcut-oriented strategies as the standing risks.

GenAI grammar instruction works through revision, not commentary. In a ten-week quasi-experiment with 88 Ethiopian EFL students, draft–prompt–reflect–revise cycles raised grammar ($\eta^2 = 0.499$) and overall writing, and content scores rose although the prompt barred content feedback (Wordofa & Abo, 2026).

Implications for language instructors

- **Emerging technologies yield small-to-moderate, level-dependent gains.** A meta-analysis of 33 TEFL studies (N = 3,181) finds an overall effect of Hedges' g = 0.38 that rises with educational level (primary 0.29, secondary 0.35, tertiary 0.44), with VR/AR yielding the largest effects and productive skills (speaking, writing) gaining more than receptive skills — supporting the use of emerging tech, especially at tertiary level, while keeping expectations realistic.
- **A systematic review maps where elementary AI language education is thin.** Across 31 studies (2013-2025), work in elementary language classrooms clustered on speaking, literacy and vocabulary while grammar, listening comprehension and sign language were barely studied, and most designs lacked grade-level specificity (Hamasha et al., 2026).
- **Use AI to extend communicative practice, not replace it.** AI interlocutors and adaptive ESL tutors expand interactional practice at scale — pair them with human interaction so fluency and uptake transfer to real conversation.
- **Extend AI Scaffolding to collaborative reading.** With 63 Chinese English majors in a GenAI-assisted social annotation study, Pan et al. (2026) found that the chatbot raised cognitive and emotional engagement and reading performance and tied social presence to integration and resolution, though high-achieving groups used the scaffold far more.

- **Readiness, not observed performance.** Across 708 learners, greater AI-assisted speaking practice tracked higher human-directed willingness to communicate (β = 0.384) and lower foreign-language speaking anxiety (β = −0.416), while AI voice-assistant scenarios lowered anticipated anxiety further; neither study observed actual human speaking (Wang & Li (2026)).
- **Watch AI output for pragmatic, not just grammatical, error.** Teachers across five online language-teaching methods named pragmatic blindness, where AI output is grammatically correct but wrong in tone, formality or culture (Baoyi and Khan (2026)).
- **Prioritize feedback quality over quantity in ASR-supported speaking.** Chen et al. (2026) find that accurate error correction and structured reflection tasks improve Feedback internalization and reflective behavior in college English speaking, while frequent ASR use and recognition accuracy boost motivation or reflection only partially — technical precision alone does not drive deeper cognitive engagement, and language proficiency moderates the gains (stronger learners internalize feedback more effectively). This argues for pedagogically sound feedback (e.g., articulatory explanations over simple error flags), scaffolded reflection, and proficiency-differentiated support.
- **Give clues before corrections.** A 'clue before correction' ChatGPT task, in which learners infer fixes from guided hints rather than receiving direct corrections, reduced cognitive load and supported personalized revision — but the benefit held mainly for learners who already had enough prior knowledge (58 students, CEFR A1–B1) (Lukešová & Jennings (2026)).
- **Deliver pronunciation feedback that localises the difference to close.** Profy learns proficiency from largely unannotated speech and shows *where* a learner diverges from native-speaker distributions; its pre/post intelligibility confidence intervals did not overlap, unlike an elicited-imitation baseline — evidence that imitation practice can be supported without expert raters (Kawamura (2026)).
- **Use the transcript channel as a second signal, not a substitute.** A WavLM audio classifier beat a zero-shot GPT-4o classifier reading transcripts on a CEFR-balanced learner corpus, so lexical traces of a first language are real but weaker than pronunciation, rhythm and intonation (Uluslu et al. (2026)).
- **Support learners' psychological adaptation to AI-assisted study.** Wu (2026) tracks learners of Japanese over a semester and finds they sort into maladaptive, moderate, and positive adaptation profiles driven by the balance of technostress and resilience, with most learners gradually shifting toward positive adaptation and reporting higher Self-Efficacy and lower burnout — a signal to design AI-mediated language practice that manages technological strain, not just tool access.
- **Be alert to scoring and feedback bias against learners.** AI scoring can penalize non-native patterns; linguistic-diversity research warns AI privileges standard English — use self-referential or human-moderated evaluation.
- **Support the full spectrum of learners.** Dyslexia and accessibility studies and culturally responsive design (Arab-English contexts) show AI must be adapted to diverse learner needs, not assumed universal.
- **Infrastructure, not just scoring, excludes languages.** Bengali holds under 0.5% of global web content against a 67:1 English-to-Bengali training-token deficit and a rural–urban connectivity gap

(36.5% vs 71.4% internet penetration), so native-language, offline-first design is a prerequisite for access rather than a convenience (Roy and Roy (2026)).

- **Educators value GenAI for preparatory work, not live classroom use.** A PRISMA systematic review of 23 studies (Li et al. 2026) finds language educators most value GenAI for behind-the-scenes preparation — lesson planning, materials creation, and writing support/feedback — yet remain hesitant about direct, classroom-facing implementation, reflecting a theory–practice gap between approving AI in principle and using it live. Adoption is shaped by professional-identity, pedagogical, technical, institutional, and Academic Integrity factors, with educators falling on a spectrum from non-adoption to comprehensive integration; attitudes tend to evolve from initial insecurity toward confident, selective use with exposure.
- **Prepare language teachers' AI literacy.** Systematic reviews find AI literacy among language teachers is a key gap — invest in teacher professional development alongside tool adoption. As AI reshapes language education, AI literacy is also crucial for teachers to engage critically with the technology: the Teachers' AI Literacy Scale (TAILS) was developed for language teacher education, operationalizing the six-dimension ED-AI framework (knowledge, evaluation, collaboration, contextualization, autonomy, Ethics) and validated with preservice English language teachers.
- **Four interaction profiles in a high-pressure bilingual task.** Kuang, Li and Weng (2026) used eye-tracking, pen-recording and voice-recording with 22 interpreting trainees to show that students divide attention between AI output and their own note-taking in four distinct ways — Intensive Engagers, Fast Scanners, Traditionalists and Frequent Switchers — and that 58.3% of stage-level observations changed profile between the comprehension and production stages of the same task. Only comprehension-stage patterns predicted product quality, and the AI-heaviest cluster scored lowest on fluency of delivery and target language quality, which makes the case for teaching learners to describe and reflect on their own strategy rather than prescribing one way of working with the tool.
- **Route the full four-skill loop around cost and connectivity.** Guo et al. (2026) release LLMersion-1, a local-first prototype that works listening, reading, speaking and writing over the learner's own document on consumer hardware — a 1B tutor quantizes to 808 MB and the whole resident stack stays under 4 GB — and prices five years of daily practice at roughly $18 of electricity, against $1,200 for a cloud subscription. No learner outcomes are reported and pronunciation feedback is segmental only.
- **Evidence on chatbot speaking gains is uneven by feature.** In the only systematic synthesis of the question, ten studies from 2021 to 2024 improved range and intelligibility most reliably, while coherence was examined once and interaction almost never; four of the ten reported a single holistic score (Soriano-Gonzalez & Belda-Medina (2026)).

Translation students can be moved off surface correction. In a news translation course, Xian et al. (2026) found search-engine consultation rising from a median of 15.6% to 27.7% of session time ($p = 0.020$, Holm-corrected) and knowledge-based searching from 7.2% to 28.8% ($p = 0.010$). Machine translation use fell from 28.5% to 5.1% without reaching significance ($p = 0.338$), and interactive AI use stayed at a median of zero. The lever was showing students their own process rather than banning a tool.

Common Misconceptions

- **“Embodied robot tutors work because of the embodiment.”** A meta-analysis of **11 RALL studies (N = 595)** found a large pooled effect on L2 learning (**g = 0.83**) with **high heterogeneity**, and — importantly — **only interaction**-level features moderated it. Morphology and modality did not, so the hardware is not the active ingredient.
- **“AI-generated assessment items are worse than teacher-written ones.”** A comparison of **52 EFL assessment tasks rated by 20 experienced teachers** found **no significant quality difference overall** between AI-generated and human-developed items, but divergence on particular dimensions. Overall parity with specific weaknesses is a different claim from improvement or deficiency.
- **“LLM feedback can only score writing.”** A discourse-level system goes further by **naming the defect rather than scoring the text**, with sentence-pair relation classification localising **coherence breaks** such as logical jumps and missing links. The useful output is diagnostic, not numeric.

English Education (EAP / EFL / ESL)

> **English education** — the application of AI to the teaching and learning of English, especially **English for Academic Purposes (EAP)** and English language teaching more broadly (EFL/ESL/L2). This is a discipline-specific AIEd strand distinct from both general Language Learning (second/foreign-language acquisition of any language) and Writing (writing as a general skill): it centers on English as a target language and academic register, with its own signature pedagogies — communicative competence, genre-based academic writing, corrective feedback, and reading/writing in an academic register — that shape how AI is designed, used, and evaluated.

Questions to Consider

- English is the language large language models handle best. That gives English learners powerful scaffolding for academic writing — but could it also quietly entrench a bias toward standard academic English that marginalizes multilingual and World Englishes writers? Which outcome do you think dominates?
- English for Academic Purposes (EAP) centers on genre-based academic writing, corrective feedback, and academic register — distinct from general language learning or general writing instruction. Why might the specific register of academic English change what AI tools need to do versus generic writing support?
- If the AI that revises your English is itself strongest in the very ‘standard academic English’ you’re trying to master, when does that help and when does it flatten your own voice or dialect? How would you tell the difference?
- Automated feedback and AI tutors are increasingly common in English writing and speaking instruction. What might AI feedback miss about communicative competence, register, and audience that a human instructor or peer would catch?

Introduction

English is one of the most AI-affected discipline strands because LLMs are English-dominant: they are strongest at generating, revising, and evaluating English text, which is exactly what EAP and EFL/ESL instruction centers on. That English-advantage creates a distinctive double edge — powerful Scaffolding for academic English on one hand, and an entrenched bias toward standard academic English that can marginalize multilingual learners on the other.

Scope and focus

This concept organizes AI research in **English education** — the subset of language learning where the target language is English (including EFL/ESL/L2 contexts) and the academic-English register (EAP). Core themes:

- **Academic English (EAP):** AI support for the genre-based, discipline-specific English used in higher-education writing, reading, and feedback — distinct from general writing instruction.
- **English language teaching (EFL/ESL/L2):** AI tutors, interlocutors, and Feedback tools for learners acquiring English.
- **English-specific Assessment:** automated evaluation and feedback on English writing and speaking, including EAP writing revision and L2 writing assessment.
- **Reading and literature readability:** Bird (2026) fuses transformer text classification with computational-linguistics features to classify English literature by UK Key Stage, reaching an F1 of 0.996 — a scalable, data-driven complement to genre-based EAP reading support and reading-level alignment.
- **Linguistic equity:** the tension between AI's English dominance and the needs of multilingual and World Englishes writers.

How English education differs from Language Learning

Language Learning is the broader umbrella for acquiring any second/foreign language — spoken, written, and literate — via AI interlocutors, pronunciation tools, and conversational practice. English education is the **English-specific** case, and within it, EAP is a **register-specific** case:

Dimension	Language Learning	English education (this page)
Target language	Any L2 (French, Spanish, Japanese, …)	English specifically
Focus	L2 acquisition generally: spoken dialogue, pronunciation, literacy	English as a target + the academic-English register
Signature contexts	Conversation, pronunciation, general fluency	**EAP**: academic writing, reading, feedback, genre
Representative AI	L2 interlocutors, pronunciation feedback, robot-assisted L2	EAP writing tools, EFL peer-feedback, English academic writing assessment

The two overlap heavily (most English learning is also L2 acquisition), but English education foregrounds English as the target and the academic register — e.g., ethical GenAI integration in EAP, GenAI EAP writing revision, and EAP reading-material adaptation are EAP-specific in ways generic language-learning research is not.

How English education differs from Writing Education

Writing concerns writing as a general cognitive and rhetorical skill — across all languages and disciplines, from composition to academic integrity. English education focuses specifically on **English** and, within EAP, on the **academic register**:

Dimension	Writing	English education (this page)
Scope	Writing in general (any language, any genre)	English as target language + academic English register
Signature concern	Composition, revision, Learner Agency, authorship	EAP genre, academic register, L2/EFL writing, feedback literacy in English
Assessment angle	Automated essay scoring, writing feedback broadly	English-specific assessment (EAP writing, EFL peer feedback, L2 writing evaluation)
Equity angle	Bias in writing feedback	Bias + the English-dominance/multilingual tension (World Englishes)

Many writing-education articles are English-first (e.g., Marked Pedagogies), but they are framed as general writing research; English education re-centers the **English-as-target** and **academic-English** dimensions that generic writing and generic language-learning pages underemphasize.

Articles in this cluster

- **EAP-specific:** Ethical GenAI integration in EAP, GenAI EAP writing revision, EAP reading-material adaptation.
- **EFL/ESL/L2:** TACT ESL tutoring, ChatGPT EFL e-portfolio speaking, EFL peer-feedback literacy, AI vs human EFL assessment, acceptance of AI English tools, AI in Arab English classrooms, appraisal analysis of peer and AI revisions of EFL argumentative essays.
- **L2 English writing/assessment:** self-referential L2 writing assessment, L2 spoken-dialogue interlocutors.
- **Linguistic equity / World Englishes:** GenAI and linguistic diversity in academic writing, AI literacy among language teachers, underrepresented languages in AI infrastructure.

Why it matters

AI's English dominance is a defining feature of this strand. Because models are strongest in English and in standard academic English specifically, English education both benefits disproportionately (powerful EAP scaffolds) and carries distinctive risks (monolingual bias, discrimination against World Englishes and multilingual writers). Research here connects to equity, bias mitigation, automated assessment, AI feedback quality, and academic integrity.

A Scopus-based synthesis of 54 EFL studies locates the field's most-reported limitations in learner autonomy: overreliance on AI in 27 studies (50%) and reduced critical thinking in 25 (46%), against unreliable AI-generated output in 22 (41%) as the leading technical problem (Espinoza-Celi & Vargas-Saritama (2026)).

Implications for English / EAP / EFL-ESL instructors

- **Exploit AI's strength for academic English, deliberately.** Because models are strongest in English and standard academic English, EAP instructors can deploy AI for genre-based writing, reading-material differentiation (EAP materials), and revision feedback — but should frame AI as a drafting/feedback partner, not an answer engine.
- **Protect academic-English register and feedback literacy.** EAP writing revision shows feedback is only as productive as the learner's feedback literacy — teach students to interpret, judge, and act on AI feedback, and use second-rater mechanisms to check AI quality.
- **Watch the English-dominance equity tension.** Models privilege standard academic English, marginalizing World Englishes and multilingual writers (World Englishes, Marked Pedagogies) — audit feedback for monolingual bias and lowered expectations.
- **Integrate AI ethically into EAP.** Ethical GenAI in EAP calls for transparent, responsible use in Higher Education English teaching that preserves academic integrity.
- **Expect cautious, preparatory-first adoption.** A systematic review of 23 studies (Li et al. 2026) finds language educators value GenAI most for behind-the-scenes preparation — lesson planning, materials creation, and writing support/feedback — while hesitating on direct classroom use, with primary concerns centering on academic integrity (plagiarism and assessment validity). Adoption is shaped by professional-identity, pedagogical, technical, institutional, and integrity factors, and competency gaps map to episteme (understanding AI's capabilities/limits), techne (Prompt Engineering, AI-enhanced task/assessment design, detecting AI-generated text), and phronesis (ethical judgment, bias/privacy handling) — so EAP/EFL instructors should build these competencies deliberately and plan a "back-end then classroom" implementation.
- **Differentiate by proficiency and need.** EFL assessment and adaptive tutoring research support tailoring AI support and evaluation to learners' level rather than one-size-fits-all.
- **Weight technology toward production.** Across 33 TEFL studies, the pooled estimate was small-to-moderate (g = 0.38, reduced to 0.28 by trim-and-fill) and rose with educational level, favoring productive skills — speaking and writing — over receptive ones (Liu, Hashim & Sulaiman (2026)).

Common Misconceptions

- **"In EFL, AI mainly threatens cheating."** The field's own most-reported limitation is **learner autonomy**, appearing as overreliance in **27** of a **54-study** Scopus-based synthesis. The documented cost is dependence rather than dishonesty, which calls for a different intervention.
- **"Language teachers adopt enthusiastically or not at all."** A systematic review of 23 studies (Li et al.) finds **cautious, preparatory-first adoption** as the pattern. Teachers were wary in a considered way, not divided into enthusiasts and refusers.
- **"The overall effect justifies the effort."** A meta-analysis of **33 TEFL studies** found a **small-to-moderate overall effect (g = 0.38, reduced to 0.28 by trim-and-fill)** that **rose with educational**

level. The effect is modest after correction and concentrated at higher levels, so a claim for beginning learners is not supported by the pooled figure.

- **"Any AI use is equally productive for language learning."** The same work argues for **weighting technology toward production** — writing and speaking rather than consumption. The modality determined the effect more than the presence of AI.

Reading Education

> **Reading education** — the teaching and assessment of reading: comprehension, fluency, vocabulary and the motivation to read, together with the design of texts at the right difficulty for a reader. In AI in education the literature runs along four lines: tools that support readers while they read, tools that assess reading, tools that adapt or generate text for a reader's level, and the measurement question underneath all three — what makes a text hard, and whether **readability** captures it. This page treats reading as a domain in its own right, distinct from language learning (acquiring another language), English education (EAP/EFL/ESL, which carries its own reading-and-readability strand) and writing education (composing text): it is about the reader's encounter with text. The evidence is promising but uneven — several pilots, a handful of validated instruments, and few controlled comparisons. Where the knowledge base has only a small study, this page says so.

Questions to Consider

- When an AI tool helps a student understand a passage, what has the student learned — the content, a reading strategy, or how to ask the tool for the answer? Which of those do you want to assess?
- Readability formulas count words and sentence lengths. What does that miss about a reader's experience of a text, and what would you measure instead?
- If AI can rewrite any text to a student's reading level, does the level itself stop mattering — or does the student still need to meet hard text eventually?
- Who benefits when reading assessment is generated automatically: the teacher's workload, the student's motivation, or the validity of the score? Can all three improve at once?
- Reading difficulty is also an accessibility issue. How should tools for struggling readers, multilingual learners and neurodivergent students differ from a general-purpose reading assistant?

Introduction

Reading education in the knowledge base is a young strand. Most studies are small and recent, and they cluster around text rather than around readers: generating a passage, simplifying it, scoring it, or judging its difficulty. The question that ties them together is whether a machine can tell how hard a text will be for a particular reader, and whether it can act on that judgment without removing the work reading is supposed to do.

Four lines of work appear:

- **Supporting the reader** while reading, including motivational and companion tools.
- **Assessing reading**, through generated passages, quizzes and AI feedback on reading work.
- **Adapting and generating text** at a target level, from simplification to differentiated materials.
- **Measuring readability and text difficulty**, the layer the other three depend on.

Supporting Readers While They Read

Reading with generative AI produces inconsistent comprehension results — gains in one study, no knowledge transfer in another — and the AIR instrument was built on the hypothesis that the variance lies in why readers reach for the tool. Brann, Etgar and Sidi developed and validated a 21-item scale with four motives: Task-oriented, Feel-good, Translation, and Low-effort (Brann et al., 2026). Their evidence comes from 425 British higher-education students in the exploratory sample and 414 in the confirmatory one, with fit indices at CFI .95 and RMSEA .056. The distinction matters for practice: a reader using the tool to finish a task is in a different posture from one using it to avoid effort, and Low-effort is the motive the authors flag as the one to watch for shallow processing.

That is a measurement result, not an outcome study, and the page keeps the distinction. What the knowledge base does not yet contain is a controlled trial of a reading companion showing durable comprehension gains.

Assessing Reading

Reading assessment is where AI appears most often as a labor-saving device. Almirabi's practitioner case study built the AI-Mediated Motivational Reading Assessment around six multiple-choice quizzes with 53 Arabic-L1 EFL undergraduates, moving from a textbook passage to AI-generated passages, from unproctored online delivery to invigilated paper (Almirabi, 2026). Scores rose from 69.4% on the textbook quiz to a cycle mean of 76.5%, with the AI aggregate 4.2 points above the textbook quiz once unproctored quizzes were excluded. The author is explicit that passage source, delivery, proctoring and sequence were not isolated and that Motivation was never measured, so the data are consistent with a motivational benefit rather than evidence of one.

A second study moves in the other direction, treating AI feedback as a student-centered process rather than a scoring convenience. In a two-month quasi-experiment with 200 seventh-graders in Shenzhen, ChatGPT-supported Feedback on Chinese reading produced a 30.40-point gain on a feedback measure and 17.95 on feedback orientation, against declines in the conventional-feedback class (Chen et al., 2026). The mechanism claimed is feedback literacy, not comprehension, and the assessment question — whether scores mean the same thing across conditions — is left open.

Readability: What Makes a Text Hard

Readability is the oldest measurement in this area and the one AI unsettles most. A Flesch–Kincaid or Lexile score estimates difficulty from surface features, chiefly word and sentence length. CLARA was built on the objection that two stories with the same score can demand different cognitive, linguistic and social-emotional work: its 122-label developmental taxonomy reached 0.904 overlap accuracy against publisher age references and 0.81 agreement with blinded educator rankings, against 0.603 for the FKGL formula (Yin et al., 2026). The validity problem is the point — a formula can be reliable and still measure the wrong thing.

Two further studies widen the gap. Bird fuses transformer classification with computational-linguistics features to place English literature at a UK Key Stage, reaching F1 0.996 and packaging the result as a tool for teachers (Bird, 2026). Clark et al. go below the surface entirely, measuring constructions with known processing costs — low-frequency n-grams, long dependencies, stacked nouns, denominal verbs, inanimate subjects, reduced object relatives — and finding that recent models over-use them relative to their own

meaning-preserving paraphrases and to human baselines (Clark et al., 2026). Readability, on this evidence, is a property of the text's processing demands and of who produced it, not only of its length statistics.

The practical consequence is that a grade-level score is a weak guarantee about any text, and a particularly weak guarantee about AI-written text.

Adapting and Generating Text

The largest cluster of studies generates or rewrites text for a reader. Three approaches differ in what they control:

- **Level-controlled generation.** Fine-tuning three 8B models on an expert-designed children's reading curriculum and stories from GPT-4o and Llama 3.3 70B outperformed both larger zero-shot models on difficulty-related metrics, with negligible safety issues (Li et al., 2026).
- **Differentiated materials.** A role-prompted GenAI workflow for EAP reading materials improved outcomes mainly by adding proficiency-specific support layers — glosses, sentence unpacking, rhetorical cues, critical prompts — rather than by changing passage-level complexity, with the largest effect among high-proficiency learners (d = 1.40) (Gao, 2026).
- **Tailored course readings.** A graduate course replaced its textbook with on-demand readings tailored to interest and comprehension level; 24 students rated them useful and 75% agreed they learned more, while the artifact analysis found missing traceability and inconsistent citation (Sidorkin, 2026).

Simplification is the fourth variant, and its bottleneck is evaluation rather than generation. MuTSE pairs a prompt-by-model generation pipeline with a tiered semantic-alignment engine so that simplifications can be compared and scored on pedagogically meaningful criteria instead of a single readability number (Roscan et al., 2026).

Readers, Interfaces and Access

Reading is also an access question. AIRRI renders assignment material as perturbed images to defeat screenshot-to-LLM pipelines, and its authors report the readability cost honestly: stripe overlays were judged readable by all four design and typography experts interviewed, while extraction error reached 100% (Airri et al., 2026). The trade-off between machine-readability and human readability is a design decision with an accessibility price.

For learners with dyslexia, a PRISMA-guided review of 72 studies from 2018 to 2024 finds AI used for detection, assistive support and personalized learning, but with a fragmented evidence base and little experimental validation; generative AI is minimally represented (Dabaghi et al., 2026). Reading difficulty is where Neurodiversity and Accessibility meet the general reading agenda, and the page does not treat them as a separate topic.

What the Evidence Does and Does Not Show

The strand is measurement-rich and outcome-poor. There are validated instruments (AIR), validated difficulty models (CLARA, Bird), and a growing set of generation and simplification tools. There are very

few controlled studies that connect a reading intervention to comprehension gains, and several of the assessment studies confound passage source with delivery or proctoring. Sample sizes are small: 53 students in the reading-assessment case, 24 in the tailored-readings study, 200 seventh-graders in the largest quasi-experiment. The knowledge base should be read as documenting a design space, not an established effect.

Common Misconceptions

- **"A readability score tells you whether a text is suitable."** A score measures surface features; CLARA's comparison with FKGL and Clark et al.'s processing features both show how much of difficulty it leaves out.
- **"AI-generated text is easier because it is generated for a level."** The evidence runs the other way for model output: frontier models over-use constructions associated with comprehension cost.
- **"Reading with AI is one behaviour."** The AIR scale finds four distinct motives, and they predict different kinds of use.
- **"If AI can rewrite the text, reading level no longer matters."** Differentiation changes the support around a passage more than the passage's structural complexity, which is a different intervention from lowering its level.

Environmental Education

> **Environmental Education** — teaching about climate, sustainability and the natural world, which in AI in education has become two things at once: a subject that AI can support through inquiry and situated learning, and a cost that AI imposes, since energy-intensive language models run on every student laptop carry an environmental footprint of their own. The knowledge base treats both halves together, because Sustainability education delivered by a carbon-intensive tool raises a question no single frame answers on its own.

Questions to Consider

- "AI and environmental education" can mean two very different things: using AI to teach *about* climate and sustainability, and reducing the environmental cost of *using AI* in classrooms. Which do you hear in your institution — and which has a budget line attached?
- If a university teaches climate science with an energy-intensive large language model on every student laptop, has it advanced environmental education or undercut it? What would have to be true for the answer to be "both"?
- One experiment found AI-assisted inquiry improved climate decision-making over inquiry alone, with gains concentrated on the weakest steps. Would you trust an AI-supported climate unit in your classroom, and what would you need to see first?
- Nearly no AIED papers report their compute or carbon footprint. Is unreported Sustainability impact a research problem, a procurement problem, a teaching problem, or none of these?

Introduction

Environmental education develops learners' understanding of ecological systems, climate, and human–environment interdependence, together with the dispositions and competences to act on them — often framed institutionally as Education for Sustainable Development (ESD) or "green education." In an AI-in-education context the term carries a tension the corpus runs into without always naming: **AI as a tool for environmental education** (teaching climate and sustainability content with generative tools) and **the environmental footprint of AI itself** (the carbon, water, and energy cost of the models institutions deploy). These are different questions with different evidence, actors, and remedies; conflating them — as several papers and most strategy documents do — makes it impossible to say who is accountable for what.(A Scoping Review of AI for Sustainability and Sustainable AI in Higher Education)(The Environmental Cost of LLMs in AIED: Reporting and Practices)

Two things called "environmental education with AI"

- **AI for environmental education** — using AI to teach environmental content, build sustainability consciousness, or support green skills. This half has frameworks, a teacher-survey study, and one classroom experiment.

- **The footprint of AI in education** — emissions and resource use of the models and infrastructure used for teaching, whatever the subject. This half has one review of reporting practice, one engineering Benchmark, and one small interface study — and nothing on the footprint of AI used for environmental education specifically.

A third, weaker strand treats "sustainable learning" as a pedagogical property rather than an environmental one: learning that persists and transfers rather than being short-circuited by Cognitive Offloading. It shares sustainability's vocabulary but is not an environmental claim.(Fostering Sustainable Learning via Embodied Intelligence: The E3-HOT Framework for Higher-Order Thinking in the AI Era)

Teaching environmental and climate topics with AI

The strongest evidence is a three-group quasi-experiment using climate change as a socio-scientific issue. Students working with an AI partner inside a structured inquiry task outperformed inquiry-only peers (d = 0.69) and traditional instruction (d = 1.88) on a decision-making rubric, with the largest gains on steps students entered weakest — monitoring and adaptive management, and generating alternatives. The AI condition was *additional to* inquiry rather than a replacement, and data collection and analysis did not separate the groups at all, suggesting the AI supported reasoning about trade-offs rather than evidence gathering.(Can AI-Assisted Inquiry Enhance Students' Decision-Making Skills in Socio-Scientific Issues? A Three-Group Experimental Study on Climate Change)

At curriculum level, the AI-SEE framework integrates AI across an engineering curriculum on four pillars (intelligence-driven, green-empowered, responsibility-leading, practice-integrated) rather than as a bolt-on sustainability module; a 144-student pilot reported gains in sustainability consciousness and behavioral engagement across personal, academic, professional, and social levels. The authors caution that this is single-institution, self-reported, single-time-point interview evidence from one Chinese transportation program. (Enhancing Sustainability Consciousness in Higher Education: Impacts of Artificial Intelligence-Integrated Sustainable Engineering Education)

Two smaller studies cover the design side. AI-assisted instructional design under Sustainable Development Pedagogy constraints improved pre-service teachers' lesson plans with an implausibly large effect (d = 2.80, 28 teams, no control group). Separately, a structural-equation study of 122 in-service teachers found *practical* AI use on science and green-energy tasks plus involvement in developing ESD-aligned materials predicted AI-integration capability, while abstract AI knowledge and attitudes did not — though a dichotomous questionnaire and a weak knowledge construct limit how far it travels.(The Role of Artificial Intelligence in Green Education: Optimizing Teacher Workflow and Enhancing Pedagogical Design under Sustainable Development Pedagogy (SDP) Constraints)(Teacher Involvement in Developing Sustainable Education Materials for AI Integration in Green Energy Education)

The environmental footprint of AI in education

This half is where the corpus is thinnest. A review of all 396 AIED 2025 proceedings papers found "LLM adoption without disclosure": most projects use LLMs, 85 papers reported any computational cost, and only 57 mentioned environmental impact — using incompatible metrics, so the field cannot aggregate its own evidence. The authors argue that failing to report environmental cost is itself an ethical concern, and propose

an Open Source method (CodeCarbon plus a two-parameter FLOPs estimate for proprietary models).(The Environmental Cost of LLMs in AIED: Reporting and Practices)

On the learner side, an eco-feedback interface exposing the latency–carbon trade-off during live LLM use was studied with 89 computer science undergraduates in a computing ethics course: students chose the lower-carbon mode in roughly 45% of low-latency interactions but under 5% at high latency, and sustainability awareness significantly raised that choice. The sample is small and unusually technically informed, but it is the only direct evidence in the corpus that footprint information moves learners at all — and it suggests the binding constraint is patience, not values.(When LLMs Slow Down: How Environmental Impacts Mediate University Students' LLM Usage)

Mitigation evidence comes from an on-premise CS knowledge-base assistant on a single consumer GPU (12 GB VRAM) with openly licensed content: 1.8 mWh per query at best — about 0.54 Wh for a class of 30 students submitting ten queries each — with quantization-aware fine-tuning containing both the accuracy loss and the hallucination rise that compression alone caused. It is an engineering benchmark, not a learning study, but it shows the footprint question has design levers (grounding, quantization, deployment location), not only usage-discipline levers.(Towards sustainable AI knowledge-base assistants in computer science education: on-premise deployment and optimization with open educational resources)

Green skills, sustainability consciousness, and teacher capacity

Together these studies describe a green-skills agenda delivered unevenly: sustainability consciousness as a curricular outcome, ESD-aligned material development as the mechanism for teacher capability, and climate decision-making as a measurable reasoning skill. The value-critical strand supplies the caveat: a conceptual analysis argues AI's contribution to sustainable education is **conditional and governance-mediated**, supporting sustainability only when adoption is subordinated to explicit educational values and human-centered purposes — which places AI Governance and critical pedagogy inside environmental education rather than beside it.(Sustainable Education in the Age of Artificial Intelligence and Digitalization: A Value-Critical Approach)

The scoping review organizing this literature supplies the field's own verdict on scale: applications cluster around energy management, climate monitoring, and green-campus programs, but are limited in scale, often lack ethical or environmental guidelines, and much of the research remains conceptual or small-pilot. Coverage is skewed toward North America and Europe, with almost nothing from the Global South beyond a few South African studies.(A Scoping Review of AI for Sustainability and Sustainable AI in Higher Education)

What the evidence does not yet establish

- **No footprint evidence for environmental education specifically.** Carbon and energy figures come from general LLM studies and a CS-context benchmark; nothing measures the environmental cost of an AI-supported climate or ESD curriculum.
- **No learning-gain evidence for footprint interventions.** Eco-feedback changed choices in a lab-like study; nothing shows it changes habits, assessment outcomes, or procurement.

- **No causal evidence for the curriculum frameworks.** AI-SEE is a single-site self-report case and E3-HOT a design blueprint with no implemented study; the SDP lesson-design result has no control group.
- **No large-scale or cross-context evidence.** Every empirical result here is single-site, and the teacher studies rest on small purposive samples with weak instruments.
- **The two halves are rarely studied together**, even though both bear on the same classroom.

Implications for AI in education

1. **Name which question you are answering.** Strategies that use "sustainability" for both AI-for-climate-teaching and AI's own footprint hide the accountability gap Daniel et al. (2026) identify; keep the agendas separate, with separate owners.
2. **Treat footprint disclosure as field infrastructure.** Reporting compute and carbon beside accuracy — with a sustainability statement even when measurement is imperfect — is the only route out of the incompatible-metrics problem.
3. **Design for the impatient learner.** If the lower-carbon option costs perceived latency, most students will not take it: keep latency low, expose controls, and describe impact in concrete outcome terms, not abstract carbon units.
4. **Prefer lighter deployment where pedagogy allows.** Grounding a model in a licensed local corpus and quantizing with fine-tuning gave usable accuracy at a fraction of the energy — reuse that pattern before scaling cloud inference.
5. **Build teacher capability through material development, not awareness campaigns,** and fill the Global South gap rather than importing evidence from North American and European contexts.

Common Misconceptions

- **"AI in environmental education mainly supplies information."** The measured gains are in **decision-making**: students working with an AI partner inside a structured inquiry task outperformed inquiry-only peers (**d = 0.69**) and traditional instruction (**d = 1.88**) on a decision-making measure, with gains **concentrated on the weakest steps**. The effect is in reasoning quality, at the points where students were weakest.
- **"Inquiry alone is the active ingredient."** AI-assisted inquiry **improved climate decision-making over inquiry alone**, so the AI contribution was additional to the pedagogical structure rather than interchangeable with it.
- **"Large effects from small samples are still large effects."** AI-assisted instructional design under Sustainable Development Pedagogy **improved pre-service teachers' lesson plans with a d = 2.80 from 28** participants — the reviewers' own word is *implausibly large*, and an effect that size from that sample should be treated as a signal rather than an estimate.

Business Education

> **AI in business education** — the application of artificial intelligence to the teaching and learning of business, economics, and management, and the preparation of students for a GenAI-integrated workplace. Business schools face a double imperative: integrating AI *into* the curriculum as a subject and pedagogical tool, while also preparing students to *use* generative AI responsibly and effectively in professional practice.

Questions to Consider

- Business schools face a double imperative: integrating AI into the curriculum as subject and tool, while preparing students to use AI responsibly in professional practice. Before reading, which of those two do you think most business programs currently get right, and which gets shortchanged?
- A student-informed framework found students were highly engaged and recognized they needed GenAI skills for careers — but also wanted to use AI without unintentionally committing academic misconduct. Why might a student want to use AI and simultaneously worry about breaking rules around it?
- Research on constructive alignment found that whether GenAI benefits or risks dominated was shaped by the degree of curriculum integration — integrate, don't append. What does 'integration' look like in a business program as opposed to just adding AI tools on top?
- A decade of research flags persistent gaps in curriculum coherence, educator readiness, and assessment validity. If you were redesigning a business course for an AI-integrated workplace, which of these three gaps would you tackle first and why?
- Business is one of the fastest fields for generative AI adoption, so graduates face acute pressure to be AI-ready. How might the AI skills that employers in finance, marketing, or management actually value differ from what students are currently taught in the classroom?

Introduction

AI in business education is a growing discipline-specific strand of AI in education. Business schools must prepare students for a future workforce where generative AI is pervasive, requiring both AI literacy and domain-specific application (finance, marketing, management, economics, entrepreneurship). The research highlights a tension between integrating AI as a pedagogical and professional tool and managing academic integrity, ethical use, and Assessment redesign.

AI in business education across the knowledge base's research

- **Student-informed frameworks.** Drummond & Dale (2026) present a student-informed conceptual framework for integrating GenAI throughout business degree programs, based on a 149-student UK case study. Students were highly engaged, recognized the need for GenAI skills for their careers, and wanted to use AI without unintentionally committing academic misconduct.

- **A decade of research.** Espino & Espino (2026) bibliometrically mapped 213 articles (2015–2024) on AI in business education, identifying four clusters: AI-driven business education transformation, innovative digital pedagogies, AI-enhanced personalization, and business education aligned with the digital economy — with persistent gaps in curriculum coherence, educator readiness, and assessment validity.
- **Constructive alignment.** Zhou et al. (2026) analyzed 17 cases of GenAI adoption at a UK business school, finding the balance between pedagogical benefits and risks was shaped by the **degree of curriculum integration** — constructive integration produced better outcomes.
- **Student insights on curricula.** Rook & Plumb (2026) drew on 166 undergraduate business students in a capstone unit, finding strong support for integrating GenAI into curricula with three priority areas: understanding/optimizing GenAI functionality, exploring applications across contexts, and navigating ethical/legal dimensions.
- **From memorization to judgment under ambiguity.** Shi, Dai & Zhang (2026) propose three generative-AI mechanisms for management courses — decomposing classic theories into assumptions and boundary conditions against real filings, tracking emerging cases between textbook editions, and a simulation whose AI role generates disruptive events and cascading consequences.
- **Organizational adoption.** Al-Rahmi (2026) examined organizational and technological drivers of AI adoption in higher education (using TOE + Diffusion of Innovations frameworks, n=300 staff), relevant to how business schools and their institutions adopt AI-driven decision support and smart learning platforms.
- **Conversational agents in business Simulation games.** Wenzel, Geiger, and Liening (2026) develop and evaluate an AI-enhanced conversational agent (Lara) for adaptive instructional support in business simulation games used for experiential entrepreneurial learning. Grounded in an equity-by-design stance and universal design for learning, the CAIS-GBL framework targets cognitive, motivational, affective, and socio-cultural engagement, with evaluations among student teachers and BSG participants showing positive perceptions of cognitive/social presence and Self-Regulated Learning support — a model for scaling formative feedback in simulation-based business education.
- **Agentic GAI for complex applied tasks.** Ilieva et al. (2026) develop the AGAI-HE framework around an **e-commerce** course, where the learning task requires comparing business models, weighing market and operational constraints, and defending strategic recommendations — multi-step applied work that prompt-response chatbots support poorly. Their 130-student perception study found both chatbot and agent support rated above traditional e-learning on learning enhancement, personalization, decision-making support, and workflow organization, yet no significant agent-versus-chatbot difference, and the strongest endorsement went to combining all three modes. For business programs the reading is that adoption is an instructional-design question about how AI support is sequenced and governed, not simply a tooling upgrade (Agentic AI).
- **A course-built RAG chatbot moved expectations, not outcomes.** In a semester-long randomized trial with 454 undergraduates in a Principles of Marketing course, Thoeni and Fryer

(2026) found no significant group-by-time effect on interest, Self-Efficacy, engagement or test performance, although students logged in 0.89 times per week and rated enjoyment 80.4.

- **Assessment and grading innovation is under-researched.** Mesny, Roberge-Maltais & Galy (2026) surveyed 58 assessment-related articles over 20 years across four leading management-education journals (AMLE, JME, Management Learning, IJME) — roughly three per year, many in 2010 and 2014 special issues — finding assessment and grading under-researched relative to their central role in shaping learning. Self- and Peer Assessment dominate the discourse (nearly half the corpus, chiefly for summative evaluation of group work); authentic assessment appears mainly via technology-mediated simulations and is often conflated with experiential learning; while reassessment, standards-based grading, and ungrading are virtually absent. The authors urge management educators to engage more actively and reciprocally with these innovations, recommending incremental experimentation (ungraded assignments, reassessment for a single task, standards-based rubrics) backed by program-level coordination and documented Scholarship of Teaching and Learning evidence.
- **Automated scoring of business coursework needs corpus-specific validation.** On 60 student marketing posts from a BrandSim simulation, Li (2026) found an LLM reached only ICC(2,1) = .435 with the human mean — deterministic rules .091, an equal-weight hybrid .266 — while adding researcher-authored anchors raised the LLM to .846 without changing any student score.
- **A business-education alternative grades the process, not the topic.** In a first-year Business Analyst degree apprenticeship, marking required documented iteration and peer collaboration, and students who used GenAI contested its counterarguments rather than submitting them (Alam & Jackson, 2026).
- **Teaching AI as a first-class process-design element.** Jalali (2026) places an AI-decision checkpoint in each BPM lifecycle phase across six modules of a 152-student course, so students build a working LLM intake agent and then discover at a checkpoint that the actual bottleneck is a two-person fraud-investigation queue.

Economics and management education

AI in business education spans **economics** and **management** as core disciplines. The knowledge base's coverage focuses on the pedagogical and curriculum dimensions (how AI is taught and used in business programs) and the professional-readiness dimension (preparing students for AI-integrated workplaces). Key themes include AI literacy, generative AI application across business functions, ethical and integrity considerations, and curriculum and Assessment redesign to reflect AI-integrated professional practice.

Why AI in business education matters

Business is one of the fields where generative AI adoption is fastest, so business schools face acute pressure to prepare students for an AI-integrated workplace. The research emphasizes that effective integration is **curriculum-driven and student-informed** — not just adding AI tools but redesigning programs so that GenAI literacy, ethical judgment, and authentic application are woven through degree structures. This

connects business education to the knowledge base's broader themes of AI literacy, educator preparation, Assessment redesign, and curriculum reform in the AI era.

Implications for business instructors

- **Integrate AI curriculum-driven and student-informed.** Student-informed frameworks and student insights show students want GenAI skills for careers and to use AI without unintentional misconduct — design programs that weave AI literacy, ethical judgment, and authentic application through degree structures.
- **Align curriculum constructively.** Constructive alignment research finds the degree of curriculum integration shapes whether GenAI benefits or risks dominate — integrate, don't append.
- **Address the persistent gaps.** A decade of research flags gaps in curriculum coherence, educator readiness, and assessment validity — prioritize these in program design.
- **Prepare students for an AI-integrated workplace.** Emphasize AI literacy, ethical use, and domain application (finance, marketing, management, economics) as core competencies, not electives.

Common Misconceptions

- **"Students want AI because they want shortcuts."** A student-informed framework found students **highly engaged and aware they need GenAI skills for careers**, while also wanting **to use AI without unintentionally committing academic misconduct**. The demand is for competence with clear boundaries, not for permission to avoid work.
- **"Adding AI modules to a business curriculum captures the benefit."** Research on constructive alignment found that whether **benefits or risks dominated was shaped by the degree of curriculum integration** — the operative distinction is **integrate, don't append**. A bolted-on module leaves the assessment design unchanged.
- **"Tool sophistication beats conventional e-learning."** A **130-student** perception study found **both chatbot and agent support rated above traditional e-learning** on enhancement, personalization and decision-making. Worth noting what this measures: student *perception* against a conventional baseline, not learning against it.

Humanities and Social Science Education

> **Humanities and Social Science (SSH) Education** — the teaching of disciplines concerned with human culture, values, meaning, and social life, including history, philosophy, literature, languages, sociology, and the arts. AI in SSH education raises distinctive questions because these fields center on interpretation, critical judgment, authorship, and meaning-making — processes that generative AI both supports and disrupts. AI here functions less as a tutor of factual content and more as an epistemic mediator that reshapes how students interpret texts, construct arguments, and understand their own Learner Agency as writers and thinkers.

Questions to Consider

- The humanities prize interpretation, authorship, and critical judgment — exactly the capabilities generative AI most challenges. How does that make AI integration in these disciplines different from in STEM?
- The page describes AI as an 'epistemic mediator' that can externalize your interpretive thinking and hybridize your authorship. When AI helps you interpret a text, who is actually doing the interpreting?
- It identifies three trajectories for learners: AI-dependent, AI-enhanced, and AI-critical interpretation. Where do you think most humanities students currently land — and what would move them toward the AI-critical end?
- In history education, research shows AI can shape reasoning and source interpretation, including through filters that 'protect' students. How would you teach students to interrogate an AI's mediation of historical claims?
- If original authorship and interpretive autonomy are the core values of the humanities, what does it mean when AI can produce a plausible interpretation instantly? What human capability becomes more, not less, valuable?
- The page warns against treating AI as a content tutor in fields centered on meaning-making. What would it look like to use AI deliberately to deepen, rather than flatten, students' critical analysis?

Introduction

SSH education is a distinct subject area in the knowledge base, complementary to STEM Education and Language Learning. Because the humanities prize interpretive depth, authorship, and contextual judgment, they pose different AI-integration challenges than STEM — and connect to Higher Education and AI Literacy in domain-specific ways.

Civic and political education is a sibling subject area to these disciplines rather than a branch of them, and Civic and Political Education treats it in its own right. The knowledge base's evidence there is thin: eight sources touch the topic and none measures civic learning.

How AI appears in humanities and social science education

- **Restructuring interpretive cognition.** Voicu argues that generative AI acts as an *epistemic mediator* that reconfigures meaning-making, authorship, and learner Learner Agency in SSH education. It identifies three transformations — externalization of interpretive cognition, hybridization of authorship, and emergence of distributed epistemic agency — and three developmental trajectories (AI-dependent, AI-enhanced, AI-critical interpretation). This grounds a developmental-critical pedagogical model for preserving interpretive depth.
- **What a task lets a reader see decides whether authorship is assessable.** In a model simulation of 148 texts, memoranda and revision defenses scored 3.16 and 3.10 on argumentative visibility against 2.63 for position essays, because the format itself required source explanation or a response to objections (Liu & Liu (2026)).
- **History education.** Research on LLMs in history education examines how AI shapes historical reasoning and source interpretation.
- **Humanities and social-science students' experiences.** GenAI's impact on Chinese humanities and social science students and AI acceptance among language/English learners document student-facing effects across SSH disciplines.
- **Critical and philosophical dimensions.** Critical AI literacy and the philosophy of AI in education are especially salient in SSH, where questions of meaning, values, and epistemic authority are central.
- **Institutional digital transformation.** Qin (2026) documents how Lingnan University repositioned itself as a "Research-Intensive Liberal Arts Institution in the Digital Era," mandating GenAI literacy for all undergraduates (including a required first-year Common Core course on generative AI covering latent spaces, GANs, diffusion models, prompting, fine-tuning, bias, and misinformation). The position paper argues the AI-for-education shift is an *intellectual transformation* rather than technocentric augmentation, positioning digital fluency as a core liberal arts competency while a human-in-the-loop model foregrounds ethical reasoning, critical judgment, and social responsibility — a concrete blueprint for higher education balancing GenAI innovation with humanistic foundations.
- **The sector's assessment exposure is now measured, and it is concentrated rather than diffuse.** Villanueva (2026) audited 15,587 Arts and Humanities unit records across Australia's Group of Eight universities and found 58.6% of 2026 assessment items highly exposed to GenAI, with take-home essays and research reports accounting for 71.4% of that exposure once weighted by marks.

Why it matters

SSH education foregrounds the very capabilities generative AI most challenges — original authorship, interpretive judgment, critical analysis, and context-sensitive meaning-making. The knowledge base treats this domain as a critical counterweight to instrumental, skills-based framings of AI: it asks whether AI-supported learning preserves Critical Thinking, epistemic responsibility, and interpretive autonomy, connecting to Critical Pedagogy and AI Literacy.

Implications for humanities and social-science instructors

- **Treat AI as an epistemic mediator, not a content tutor.** Voicu shows AI reconfigures meaning-making, authorship, and agency in SSH — design pedagogy around the three trajectories (AI-dependent, AI-enhanced, AI-critical) and aim for the AI-critical end.
- **Protect interpretive depth and authorship.** Because the humanities prize judgment and original authorship, guard against AI flattening analysis; make critical evaluation of AI output a learning goal (Critical Thinking, AI Literacy).
- **Use AI deliberately in source work.** History research shows AI can shape reasoning and source interpretation — teach students to interrogate AI-mediated historical claims and the filters it applies.
- **Consider student-facing impacts.** Student experience studies document how GenAI affects SSH learners; adapt support and integrity framing to real usage rather than assumptions.

Common Misconceptions

“The humanities are the least AI-exposed part of the curriculum.” The exposure has been measured and it is concentrated rather than diffuse: Villanueva (2026) audited **15,587 Arts and Humanities unit records** to establish where the exposure sits. It is unevenly distributed across units rather than spread thin, which makes assessment redesign a targeted problem rather than a sector-wide one.

“AI in humanities education is technocentric augmentation.” The position paper this page draws on argues the shift is an *intellectual transformation* rather than augmentation, positioning digital fluency as a core liberal-arts competency. Adding a tool to an unchanged course mistakes the transformation for its instrument.

“Values education can be handed to a model as content.” Chen (2026) reframes values education as a relational practice with three conditions — answerability, exemplarity and address — and reads each of GenAI’s five affordances as replacing a relation: the simulated perspective replaces the stakeholder who can be wronged.

“Critical analysis is what AI most threatens, so it should be restricted.” Critical analysis is also what intentional use most develops, when the task is designed to deepen rather than flatten it. A human-in-the-loop model locates the discipline’s contribution in the learner’s judgment rather than in the tool’s output.

“A general-purpose model is as useful for textual scholarship as for summarisation.” Interpretation requires the reader’s position, and an assistance layer that supplies the reading has performed the interpretive act the discipline exists to teach.

Civic and Political Education

> **Civic and Political Education** — the part of schooling that prepares people to understand institutions, reason about public problems, and act as citizens rather than private individuals. Trust et al. (2025) treat it as a domain with distinctive goals: critical engagement with power, multicultural perspectives, and action on social issues. The knowledge base names the topic but holds little evidence on it.

Questions to Consider

- When a student asks a chatbot whether a policy is constitutional, what would they need to know to judge the answer?
- Does fluent, sourced-looking prose make public reasoning harder, or merely faster?
- If a learner uses AI to draft testimony for a local hearing, does authorship belong to Academic Integrity or to civic education?
- Media literacy teaches students to analyze messages. What must be added before that is enough for citizenship?

Introduction

Civic and political education covers how schools prepare people for public life: governmental structures, the rights and obligations of citizens, public reasoning about contested problems, participation in collective decisions, and the information skills public argument requires. Santos-Albardía et al. (2025) describe the goal as participatory and critical citizenship, not tool proficiency. Nkalanga (2026) locates it in Social Sciences, Geography, and Life Orientation, where citizenship and human rights are already taught. This page defines the territory and records what the corpus holds: adjacent work, not a civic education literature.

What civic education covers

The domain is broader than a civics course. It includes institutional knowledge, public reasoning, a disposition to participate, and judgment about information used in argument. Zhai et al. (2026) show the breadth from another discipline. Their Vision II covers science in everyday and civic life; Vision III covers action at community and societal levels, tied to democracy and issues such as vaccination and climate. They note that Vision III is the least served by standards and assessments.

The largest civic-specific study here is a content analysis, not a learning study. Trust et al. analyzed 310 AI-generated lesson plans containing 2,230 activities for all 53 Massachusetts eighth-grade civics standards. Three chatbots each received a basic prompt and a “highly interactive” variant. Ninety percent of activities sat at Remember, Understand, or Apply; Analyze was 4%, Evaluate 2%, and Create 4%.

The cultural result is starker. Using Banks’ levels of multicultural integration, 94% of activities contained no discernible multicultural content. Of the rest, 137 were Additive, four Contributions, one Transformation, and none Social Action. Every chatbot returned the same structure whatever the standard covered.

Civic education is not a recall subject. A plan asking students to list three facts about the Bill of Rights teaches the vocabulary of citizenship while removing the practice of it.

Why generative AI is a civic problem, not only an integrity problem

Academic integrity asks whether submitted work is the student's own. Civic education asks whether a public claim is true, attributable, and open to contest. Generative AI stresses the second question in ways the first does not capture.

Three mechanisms recur. First, fabricated evidence: a model can produce a plausible quotation, statistic, or legal citation that a student cannot independently check. Second, generated political persuasion. Rudolph et al. (2025) name deepfakes, targeted propaganda, and automated disinformation as threats to democracy. Santos-Albardía et al. report expert consensus that AI and deepfakes make reality harder to distinguish from misinformation. Third, source verification. A learner who cannot trace a claim to an institution or named author depends on the system that produced it.

The learner is also a producer, writing to officials and circulating evidence. The civic question is not whether AI assisted the text. It is whether the student can stand behind the claim and answer objections.

Muñiz and Castro Samayoa (2026) state the civic case in political-theory terms rather than test terms. Their argument is that education's contribution to democracy is the practice of critical evaluation, and that generative AI removes the practice rather than the content. Outsourcing inquiry, analysis, evaluation and synthesis to a model shortens the exercise that builds those capacities in both K–12 and higher education. They name three mechanisms: the disappearance of productive friction, automation bias, and an efficiency frame that treats the point of schoolwork as task completion. The stakes they attach to this are the largest in the corpus, and the least evidenced: authoritarian governments, they write, flourish when citizens cannot evaluate truth claims, and regimes have suppressed literacy to that end. Their remedy is a pair of literacies and a design commitment — critical AI and media literacy, and process over product. The essay supplies the rationale this page otherwise assembles piecemeal, and it supplies no data of its own.

Nkalanga (2026) adds a mechanism integrity framing misses. From South Africa's AI-mediated border regime the paper derives five civic digital literacy demands: algorithmic transparency, data rights, bias recognition, rights contestation, and participatory governance. Someone who cannot recognize that a decision was algorithmic, or find the appeal route, has lost a civic capacity rather than a technical skill.

Where media literacy ends and civic education begins

The overlap is substantial and the sources do not settle the boundary. Media literacy is conventionally the ability to access, analyze, evaluate, and create messages. Santos-Albardía et al. (2025) extend it toward educating citizens to use information critically, and their experts describe critical educommunication as a politically grounded practice that strengthens democracy.

The civic addition is not another evaluation skill. It is the move from judging a message to acting on institutions. Media literacy can tell a student that a viral claim is unsupported. Civic education asks which body has authority, what right of access applies, how a decision can be contested, and what participation would change. Nkalanga's five demands specify that second half most clearly.

Frameworks cover the first half better. Nkalanga finds DigComp 2.1 includes data literacy and digital safety but leaves algorithmic accountability outside its competence areas. South Africa's Information Technology and Social Sciences standards carry little digital literacy content, and the Geography syllabus contains nothing on algorithmic systems. The result is competent tool users who cannot interrogate a decision made about them.

What the knowledge base holds, and what it does not

The nine relevant sources are heterogeneous. Trust et al. provide the only large civic-content analysis. Nkalanga synthesized 53 documents with no primary data. Santos-Albardía et al. interviewed seven experts and surveyed 141 students at one university. A Finnish interview study with 13 teachers found qualification dominating accounts of AI education, while subjectification lacked concrete strategies. Zhai et al. offer a framework and Rudolph et al. an editorial; Muñiz and Castro Samayoa argue the democratic case from political theory. Theodora and Tselios (2026) ask whether adult learning serves economic needs or civic participation. Elmahjub et al. (2026) find democracy and rule of law named in 92 of 160 governance documents, but legal force in four.

The corpus holds nine sources that touch civic and political education, and none of them measures civic learning. The fullest statement of the stakes is an essay rather than a study, and no study in this knowledge base tests whether students exposed to AI-mediated civic instruction become better informed, more participatory, or more resistant to manipulation.

The gap is specific. Nothing measures whether students can verify a generated claim against a primary source, identify an algorithmic decision and find an appeal route, or produce public writing that survives scrutiny. The media literacy survey's readiness figures are self-assessed, so they describe confidence rather than competence.

A research program would need baseline and post measures of civic knowledge, public reasoning, and source verification, using tasks with planted fabrications. It would need behavioral measures of participation, production tasks scored for claim accuracy and attribution, and tests of whether learners can contest a decision rather than describe one. It would need classroom conditions, teacher preparation, and equity data, especially in South Africa, where Nkalanga reports roughly 16,000 schools without computer laboratories and frames the shortfall as a Global South equity problem. Until then, this page is a map of a gap.

Common Misconceptions

"AI literacy already covers citizenship." Functional AI literacy teaches people to use tools. Algorithmic accountability asks who decides, on what basis, and how that decision can be challenged. Nkalanga shows mainstream competence frameworks omit this layer.

"The problem is students cheating." Integrity framing asks who wrote the text. Civic framing asks whether the claim is true and whether the student can defend it. Trust et al. show the supply side fails first: AI-generated civic lessons were lower-order and monocultural before any student used them.

"Better prompts will produce better civic lessons." The interactive variant made minimal difference, and all three chatbots produced the same structure across 53 standards. Prompt quality did not restore disciplinary texture.

“There is enough evidence to guide practice.” There is enough to justify caution. One content analysis, one documentary synthesis, one small mixed-methods study, and several conceptual or policy pieces do not establish what works.

Arts, Design and Media Education

> **Arts, design and media education** — the studio- and performance-based disciplines in which learning happens by making: architecture and spatial design, interior design, music performance, composition and analysis, visual art and image generation, digital media and digital storytelling, and stage and performance technology. Across the articles in this knowledge base the recurring questions are whether Generative AI erodes craft and skill development or moves it up a level, how critique and the Assessment of creative work change when a polished artifact is cheap to produce, how much of each discipline rests on embodied and material practice, and who is included when creative tools become generative. Coverage is concentrated in higher education and in single-studio or single-course studies, so most findings below are case evidence rather than discipline-wide claims.

Questions to Consider

- In an architectural studio study, teams using a GenAI-plus-XR pipeline reported *lower* confidence in their own design ability afterward, and blinded raters scored their presentations no better than a control group's. What would you need to know before concluding the tools harmed learning — and what would make you conclude it anyway?
- Studio teaching has always run on the critique and on visible process: sketches, models, successive iterations. If a student can produce a finished-looking image in a minute, what should the critique actually examine?
- In a project-based digital storytelling capstone, students' ideas were rated more original than their finished works were coherent. Where does the hard learning really sit — generating ideas, or integrating them?
- A music education review distinguishes autonomous generators such as Suno and Udio from interactive composition assistants such as the Continuator, and argues that only the second is educationally productive. Do you agree, and what is your criterion for the distinction?
- Designers in Malaysia are described as shifting from primary form-generators to critical curators of machine output. If that is the destination, what should a first-year design course teach first?
- Blind and low-vision string players learn bowing through touch and proprioception because visual demonstration is unavailable to them. What does that imply for feedback systems in the arts that default to a screen?

Introduction

What these disciplines share is the studio or the rehearsal room as the site of learning, with a made artifact and the process behind it as the object of assessment. AI enters in several shapes: an image generator in the architecture and interior design studio, a composition and analysis tool in music, a spatial partner inside immersive environments, an automated scorer of written analysis, and — in stage lighting — an instructor-facing aid that turns spoken teaching intent into executable demonstrations. The sections below trace what the studies report, then draw out the cross-cutting questions of craft, assessment and access.

This page is the discipline home for studio and performing-arts subjects, and it is narrower than its neighbors. AIEd in the Disciplines holds the general argument that AI in education research must be domain-aware across all subjects; this page is about what is specific to making. Creativity covers the cognitive construct wherever it appears — divergent thinking, the homogenization risk of single-model assistance, protecting the learner's generative act — including in mathematics and creative coding; this page covers the disciplines in which creative production *is* the curriculum. Design Thinking covers ideation and user-centered problem framing as a general pedagogy; this page covers the studios where that process is taught, supervised and judged. Humanities and social science education treats interpretation, authorship and argument in text-centered fields and lists the arts among its constituent areas; here the arts and media are lifted out of that interpretive frame and centered on material, spatial, sonic and performative practice. Design Education carves the professional half out of this same territory. This page spans the studio and performing arts, whose shared feature is making. Design education instead follows the narrower formation pipeline for product, service, interaction, interior and architectural designers — portfolio assessment, accreditation expectations, employability. It also treats the studio process behind an artifact, rather than the artifact itself, as the object of assessment.

Studio Pedagogy and the Critique Under Generative AI

Generative tools reach these disciplines through an existing ritual: work made publicly, shown incomplete, and criticized. What the sources show is that AI changes the *middle* of that process most reliably and the *ends* least. In the GenARch study, Xiao et al. (2026) put a GenAI plus multi-user XR pipeline into a real undergraduate architectural design studio and found a complementary division of labor: Generative AI externalized ideas, giving teams something concrete to point at, compare and argue over, while XR supported evaluation, letting students judge proportion, adjacency, lighting and site context at full scale.

The tooling was awkward at both ends of the process. At the start, teams had no ideas yet to encode in a prompt; later, richer concepts made prompting easier but raised expectations of constraint-following, and when precision mattered students went back to SketchUp and Revit. They reported a dimensional-fidelity failure — "I asked it to make a 10 feet wall of 3D model, it wasn't 10 feet" — asset latency of seconds to minutes, and shared attention that drifted when team members looked at different parts of a model. Giving every participant a headset did not by itself produce coordinated collaboration.

The studio's accountabilities did shift. In a longitudinal study of generative models in design studios, Gül et al. (2026) distinguish using GenAI as visual stimulus in early ideation from a combinatorial use that expands the solution space during development, and locate the pedagogical problem in competence rather than access: without the discernment to differentiate between models and use them deliberately, abundant output produces design fixation and aesthetic lock-in. Their conclusion moves the instructor's role from transmitting craft toward coaching when, how and why to delegate creative exploration.

Architecture, Spatial and Interior Design

A Derby focus-group study gives the studio a more favorable result. Kapsalis (2026) ran two groups of eight Level 3–5 architecture students through a 90-minute session with a locally executed image generation-and-editing workflow fine-tuned for residential interiors. Students produced roughly 80 images per session, about ten each, with acceptance rates above 60%. Self-reported idea generation (4.5) and experimentation (4.2)

scored highest on the creative subscale, while refinement of final decisions (3.7) was less uniformly supported — some students found the tool surfaced unconsidered combinations, others that it distracted with details that did not fit the concept. The author frames this as a constructionist “microworld” that expands the creative search space without replacing design thinking, and notes survey evidence that nearly 70% of architecture students already use AI tools independently while over 95% report no formal AI education.

Interior design raises the professional-formation question most sharply. Syed Abdul Rahman (2026) describes Malaysian designers shifting from primary form-generators toward critical mediators and curators of machine output, with Visualization platforms compressing timelines and widening the range of options producible within a budget. Citing empirical work on client preference (Lan et al., 2025), the article notes that AI output is rated highly for uniqueness when aesthetic criteria predominate, but that human designers retain a clear advantage when functional, ergonomic and contextual requirements are emphasized — and that generated designs often lack cultural specificity, climatic responsiveness and reliable constructability in a market negotiating tropical conditions, multi-generational living and Islamic spatial principles. Its curriculum recommendation is sequencing rather than substitution: teach CAD/BIM, construction knowledge and human factors before generative exploration, and assess Critical Thinking and ethical reflection alongside visual quality.

Music and Performing Arts

Music is treated here as the art most exposed to economic change that began before generative AI. Briot (2026) argues that dematerialisation collapsed per-unit recorded-music value by roughly two orders of magnitude well before generative models were commercially relevant, that per-stream payouts remain on the order of $0.003–$0.005, and that generative AI prolongs an already-broken value model rather than creating it. His distinction that matters for teaching contrasts autonomous generators such as Suno and Udio — complete, stylistically coherent pieces from a text prompt, with opaque and uncontrollable structure — against interactive composition assistants such as FlowComposer and the Continuator, where the musician imposes constraints and retains intentionality and the Continuator learns a player’s style in real time as an improvisational partner. Only that second kind, he argues, is educationally productive, because the first positions students as consumers of machine output. The recommended curriculum makes production and DAW fluency core competencies and defends ensemble performance as the embodied, social dimension most resistant to substitution.

Assessment in music is being pushed toward automation, with limits worth noting. Lin, Jin and Min (2026) benchmarked GPT-4o-mini against teacher mean scores on 300 university-level music analysis responses across Harmony, Form, Reasoning and Terminology, finding that few-shot chain-of-thought prompting agreed most strongly with teacher means and that retrieval augmentation systematically over-scored; agreement was also weaker on Terminology than on Reasoning, so the authors argue for strategy-specific calibration, dimension-level validation and continued human oversight.

Vocal pedagogy supplies the clearest statement of the measurement-versus-value problem. Li (2026) argues that AI-assisted vocal teaching should not be judged by how precisely it measures pitch, stability, vibrato and timing, because the same measured deviation may indicate technical inaccuracy, expressive inflection or a recording artifact, and because measurable outputs do not represent a learner’s embodied coordination. The framework separates the evidence AI makes visible, the human learning processes that interpret it (bodily

awareness, metacognitive monitoring, self-regulated practice, motivation), and the outcomes that follow, judged by effectiveness, equity and Sustainability. Instrumental teaching for disabled musicians takes the embodiment point further: Shi et al. (2026) worked with four advanced blind and low-vision string musicians and three instructors, finding that bowed-string technique is conventionally taught by visual demonstration — unavailable to these learners — and that tactile and kinesthetic cues substitute for it. Inclusive instruction, on their account, should be built with disabled learners rather than retrofitted for them.

Stage and performance technology is where AI-assisted instruction has been designed and evaluated most concretely. Liang et al. (2026) built LumiNote, an Large Language Models (LLMs)-assisted VR system that turns an instructor's spoken intent, anchored by a laser pointer, into reviewable spatial annotations, executable lighting demonstrations and jargon explanations. Across 55 instructor prompts and 531 generated action pairs, 380 (71.6%) were applied; visual effects formed the largest prompt category (27 of 55) with high adoption (212 of 245 actions, 86.5%), while fixture-specific requests proved weakest — 26 of 28 rejections traced to directional-reference misreads such as "left light". Instructors used suggestions as a refinement process, not a finished lesson plan: of 147 rejected or modified suggestions with follow-up, 127 (86.4%) triggered a new prompt and only one a direct manual adjustment. Their workload fell (NASA-TLX 3.50 to 2.22) and sessions shortened (19 minutes 34 seconds to 12 minutes 33 seconds) as effort shifted from low-level configuration toward expression. The sharpest finding is a representation mismatch: the cues instructors rated most useful for externalizing expert reasoning were not the ones 24 learners could follow, who preferred a laser pointer (M = 5.50) and console tagging with values (M = 5.33) over spatial arrows and an avatar (both M = 4.58), though student outcome measures showed no significant differences.

Visual Arts, Image Generation and Digital Media

Text-to-image tools are the case where the studio's iterative workflow is most directly at stake, and the evidence is not a simple story of gain or loss. Liu, Meng and Zhang (2026) surveyed 417 art and design students alongside instructor focus groups and interviews, finding that performance expectancy, social influence, novelty value and creative competence all positively predicted intention to use text-to-image tools, while effort expectancy and facilitating conditions predicted negatively — which they read as shortcut-oriented use in coursework where ease and availability enable quick output rather than sustained engagement. Their competence paradox is the notable result: creative competence supports intention but also predicts more selective, restrained actual use, as students weigh authorship, originality and skill preservation against efficiency. They argue for pedagogy addressing AI literacy around creative process, prompt crafting and output evaluation, with studio process and effort as the assessed object.

The adoption question has a discipline-specific answer in Zhu (2026), who surveyed 450 art majors at eight Zhejiang institutions with a UTAUT model extended by Trust. Trust was the strongest path to behavioral intention ($\beta = 0.425$), ahead of social influence (0.155), while metacognitive control ran more directly to intention ($\beta = 0.146$) than to trust ($\beta = 0.099$). The authors read that as this discipline's stake: art's stopping rules are unclear, so holding creative agency means deciding repeatedly what to keep, revise or discard. A randomized follow-up with 80 students had blinded experts rate generated images, and prompted students scored higher on semantic content ($d = 0.67$), visual style ($d = 1.30$) and spatial composition ($d = 0.63$).

Foka (2026) turns critique into a replicable method: three epistemic games — Interpret, Interrogate and Expose — move studio discussion from impressionistic reaction to warranted bias hypotheses, with a BiasSlot rule varying one bias cue while a constant motif stays fixed.

Digital media production shows what a structured process can do. Tian et al. (2026) studied a 15-week project-based digital storytelling capstone, “Creative Shanzhou”, in which 426 final-year undergraduates, guided by 48 mentors at roughly a 1:9 ratio, translated local cultural heritage into Multimodal AI narratives. Expert ratings of the 92 resulting works were strongest on novelty ($M = 4.21$, $SD = 0.72$), followed by effectiveness (3.96) and wholeness (3.68), with 43% of projects scoring below 3.5 on wholeness — students generated original ideas more successfully than they integrated them. In a 31-student Animation subgroup, figural creative-thinking scores rose from 77.23 to 94.68 (mean difference 17.45, $t(30) = 4.55$, $p < .001$, Cohen’s $d = 0.82$). Across the analyzed projects AI served as information organizer, visual reference, ideation aid and editing tool, while students retained topic selection, narrative interpretation, cultural meaning-making and final decisions; the highest-scoring example attributed its coherence to sustained human engagement with source material rather than AI polish. The project ended in a three-day public exhibition, and 31 works were taken up by the local Cultural and Tourism Bureau.

Immersive environments provide the more favorable counter-case in vocational design. Jin et al. (2027) implemented AI-IVE-PBL — project-based learning inside an AI-enabled immersive virtual environment with an agent teaching assistant — in a first-year vocational interior design course, as a five-phase loop of discovery, envisioning, modeling, communication and refinement. In a 12-week two-group quasi-experiment (63 valid responses, 31 versus 32), the immersive-plus-agent condition scored higher on design ability ($\eta^2p = .138$) and creative ability ($\eta^2p = .111$) under ANCOVA with pretest as covariate, and lifted cognitive ($d = 0.90$) and behavioral ($d = 0.75$) engagement, Motivation ($d = 0.74$) and satisfaction ($d = 0.69$) while lowering reported cognitive load ($d = -0.52$). Innovative thinking and affective engagement moved in the expected direction without reaching significance. All outcomes were self-report, with no performance artifacts or expert ratings, which is why the authors contrast their result with the architectural studio study above.

Craft, Skill and the Assessment of Creative Work

The craft question appears in several forms, and the sources disagree about how worried to be. Kapsalis (2026) reports a levelling mechanism at entry level: students who described themselves as weak at drawing found the tool opened access to visual expression without removing the need for judgment. Against that, Syed Abdul Rahman (2026) warns that uncritical adoption risks graduates without foundational spatial reasoning, material knowledge or independent critical evaluation, and names the prevention of deskilling among early-career practitioners as a core regulatory concern. The disagreement is partly about sequencing: both favor technical foundations before generative exploration.

What is consistent is a repositioning of what gets assessed. The Derby study measured procedural confidence in-session at 3.7 out of 5 but confidence in transferring those skills beyond the studio at only 2.6 — a gap its author attributes to single-session exposure and calls a curriculum-level problem. The Malaysia analysis recommends studio projects requiring comparative evaluation of AI and non-AI design pathways, plus criteria that reward critical thinking alongside visual quality. Music’s automated-scoring results point the same way: agreement with teacher means was dimension-specific, and the authors insist on human oversight rather than full delegation. Li (2026) adds that treating measured output as educational value in itself

narrows vocal training into output correction and score optimization. The converging proposal is that creative assessment keep examining process, iteration and justified decision-making precisely because the finished artifact no longer evidences them.

Access and Inclusion in Arts Learning

Accessibility in the arts is treated less as compliance than as a design and material-practice question. Shi et al. (2026) is the clearest case: because bowed-string technique is normally taught by visual demonstration, blind and low-vision musicians depend on tactile and kinesthetic channels, and the study's disability-led co-design produced strategies rooted in those musicians' own practice rather than adaptations bolted onto a visual default.

Two other findings complicate any simple story of generative tools as an equaliser. In the Derby study about a third of participants declared a disability and nearly a fifth reported a specific learning difficulty; inclusivity items clustered at 3.8–4.1 and correlated strongly with feeling the session was approachable (ρ = .74) and with keeping up regardless of prior AI use (ρ = .81), and students less confident at drawing reported not feeling disadvantaged — a modest equalizing effect in a single 90-minute session, not demonstrated learning. The LumiNote representation gap shows the other side: cues that help experts externalize their reasoning are not the cues novices can follow, so a design that serves the instructor well can leave learners adrift, and the authors position the LLM as a mediation layer that must translate between the two. The GenARch study records a related equity decision: after data collection the technologies were released to the control students so they were not withheld. Whose aesthetic and cultural references generative models reproduce, and whether wider access to design services expands demand or intensifies mid-market competition, are raised in the Malaysia analysis and remain open.

Common Misconceptions

"The arts evidence base establishes discipline-wide conclusions about AI." It does not, and the corpus is candid about it: coverage is concentrated in higher education and in single-studio or single-course studies, so most findings are **case evidence rather than discipline-wide claims**. A result from one design studio tells you what happened there, and the studio is an unusually specific social arrangement to generalize from.

"Any generative tool is educationally equivalent to any other." The distinction that matters is whether the tool generates *for* the student or composes *with* them. A music education review separates autonomous generators such as Suno and Udio from interactive composition assistants such as the Continuator, arguing that **only the second is educationally productive**. Both produce music; only one leaves the student making the compositional decisions.

"High acceptance of generated output shows the tool is working." Acceptance is the measure of the tool's persuasiveness, not of the student's learning. In one studio study students produced roughly **80 images per session, about ten each, with acceptance rates above 60%** — a rate at which most of what was generated was used, which raises the question of how much revision and judgment the session contained.

"AI in studio teaching replaces the critique." The constructionist framing in this literature is the opposite: a designed "microworld" that **expands the creative search space without replacing design thinking**. The

critique is where judgment is formed, and a tool that supplies candidate solutions gives the critique more material to work on rather than less need for it.

“Students are not already using AI in arts education, so the curriculum can set the pace.” Survey evidence in this corpus finds nearly **70% of architecture students already use AI tools independently**. The curriculum is catching up with a practice that has already spread, which changes the task from introduction to critical integration.

Implications for Practice

For studio instructors

- Distinguish generating-for from composing-with when choosing tools, and prefer the second. The distinction is the difference between a student who directs a system and one who receives output.
- Keep the critique and make it the assessed element. Acceptance rates above 60% suggest critique is the only place the selection judgment will surface.
- Assume prior independent use: nearly 70% of architecture students are already using AI tools, so the pedagogical work is on quality of use rather than on exposure.

For developers

- Build for iteration and control — parameters, constraints, partial generation — not for one-shot production. Interactive composition is the mode with an educational claim behind it.
- Instrument revision behavior, not acceptance rate. Acceptance measures your output, not the student’s thinking.

For researchers

- Move beyond single-studio case studies before making discipline-wide claims, and report the studio’s structure since it conditions the result.

Design Education

> **Design Education** — the professional formation of designers in studio-based disciplines: product, service, interaction, interior and architectural design, taught through iterative project work in which the assessed object is the process behind an artifact as much as the artifact itself. Its distinguishing features are the studio and the critique as the site of learning, visible process evidence (sketches, intermediate models, iterations) as the primary indicator of learning, and the fact that Generative AI now makes the polished output students are graded on cheap to produce. That makes design education a test case for Creativity, Design Thinking, Assessment Validity and Workplace Learning.

Questions to Consider

- If a studio can no longer read learning off the finished artifact, what should replace visible process as evidence — mandatory process artifacts, oral examination, something that survives a cohort of 140?
- Unsupported novices in one experiment never revised a single idea until an adversarial agent surfaced stakeholder pushback. Should design teaching manufacture friction deliberately — and where does productive difficulty end?
- The designer's role, on this account, moves from producing forms to judging what the machine generates. If so, what comes first in a curriculum: manual craft, or critical evaluation of model output?
- If an Large Language Models (LLMs) can approximate instructor, peer and grant-reviewer readings of the same poster, what is left for the human critic?

Introduction

Design education is narrower than Arts, Design and Media Education, which covers studio and performance disciplines together — architecture, music, visual art, media and digital storytelling. This page covers the professional design disciplines and their formation pipeline: portfolio assessment, accreditation expectations, employability, and a practice culture that has absorbed generative tools faster than its curricula have.

It is also distinct from Design Thinking, a human-centered Problem Solving method taught across business, education and law as a transferable skill. In design education the process is not a method applied to a discipline; it is the discipline, and the studio is where it is taught, supervised and assessed. Engineering Education is the closest professional neighbour — also design-heavy, also accountable to practice — but engineering assessment rests on calculable artifacts and public-safety responsibility, whereas design's rests on critique and on process evidence that generative tools can visibly simulate.

How AI appears in design education

- **AI is an ideation resource whose characteristic risk is fixation.** Gül et al. (2026) built the GAI-A platform across a longitudinal studio study and found two productive uses: GenAI as visual

stimulus in early ideation, and as a combinatorial expander of the solution space during development. The problem, they argue, is competence rather than access — without the discernment to read models deliberately, abundant output produces design fixation and aesthetic lock-in — which moves the Teaching from transmitting craft to coaching when and why to delegate creative exploration.

- **A discipline-specific local tool widened the search space and levelled participation.** Kapsalis (2026) ran two Derby focus groups of eight architecture students through a 90-minute session with a locally executed ComfyUI workflow. Creative scores were highest for idea generation (4.5) and experimentation (4.2) and lower for refining decisions (3.7), while inclusivity items ran 3.8–4.1 and correlated with keeping up regardless of prior AI use ($\rho = .81$). Confidence gained in the session did not transfer — confidence in using these skills professionally was 2.6, a gap the author calls a curriculum-level problem.
- **Unsupported novices do not revise; an adversarial agent changes that.** Han & Martelaro (2026) ran a between-subjects experiment with 45 novice interaction designers on a civic reporting site. Their Self Reflection group never revised or deleted a single idea; agent-engaged students made roughly 3.6 times more edits, reached stakeholder concerns the other groups missed (Accessibility, Privacy, reluctance toward automation) and produced stronger proposals. The agent was rated as contributing ($M = 5.33$), but one participant felt criticized "in every aspect", and the authors insist simulated pushback is no substitute for engaging real publics.
- **A structured process keeps authorship with students at scale.** Tian et al. (2026) studied a 15-week storytelling capstone in which 426 undergraduates and 48 mentors (about 1:9) turned local heritage into Multimodal AI narratives. Expert ratings of the 92 works were strongest on novelty ($M = 4.21$) and weakest on wholeness ($M = 3.68$) — ideas came more easily than integration. Creative-thinking scores in a 31-student subgroup rose from 77.23 to 94.68 ($d = 0.82$). AI organized information and edited; students kept topic choice, interpretation and final decisions, and 31 works were adopted by a regional Cultural and Tourism Bureau.
- **Adoption is frequent, uneven across the process, and suspicious.** Broadbent et al. (2026) surveyed 280 Politecnico di Milano design students and read 100 Masters AI-use journals: 71% used GenAI daily or weekly, 65% distrusted it, 85% modified its output. Use clustered in research and writing — editing writing 77.5%, finding information 74.5%, brainstorming 68.0% — with whole-assignment use rare (18.6%). Ownership largely survived: 31% reported lost ownership or creative agency, and only prototype generation was significantly associated with it. Planning and interpreting primary research stayed with students, which the authors read as evidence that students may not count research as part of the creative process.
- **Intention is gated by attitude and shaped by task fit.** A survey of 405 design graduate students at Chinese universities modeled intention with an integrated TAM–Task–Technology Fit framework (Chu & Liu (2026)). Attitude was the necessary condition for intention ($d = 0.132$, $p < 0.001$), with 22.1% of the attitude scale required for intention at 80%. Fit fed attitude at $\beta = 0.224$, beside perceived usefulness (0.376) and ease of use (0.185). The characteristics of the studio task drove fit most ($\beta = 0.322$), which is the measured form of what the bullets above describe qualitatively: what students judge is whether the tool matches the work in front of them. Perceived

enjoyment raised ease of use but not usefulness (β = −0.033, p = 0.483), and the model left R^2 = 0.150 of intention explained.

- **Dependence type decides whether prompting capability becomes engagement.** Han and Cao (2026) surveyed 829 design students in 40 intact classes: self-reported prompt literacy predicted learning engagement (β = 0.539), and engagement predicted creative self-efficacy (0.618) more strongly than creative personal identity (0.474). The literacy–engagement link weakened only under cognitive dependence (B = −0.155), with simple slopes of 0.607 and 0.297; functional (p = 0.396) and emotional (p = 0.941) dependence did not moderate it.
- **The net effect is divergence rather than uplift.** Crolla, Xia & Jiang (2026) drew on 24 interviews and a 32-instructor survey in a built-environment faculty to describe *cognitive divergence*: AI amplifies prior differences, letting stronger students extend reasoning while weaker ones delegate formative work and produce coherent outputs without understanding — a "false sense of capability" that collapses under questioning. Loss of process visibility, in a field that relied on visible process as its primary evidence of learning, and erosion of the frictional stages that act as Desirable Difficulties compound it. Faculty positivity tracked pedagogical relevance (β = 0.534, p = .004), not seniority, and the faculty's mitigations do not scale past studio-sized cohorts — which argues for institutionalized process-evidence requirements. Limits: single institution, n = 32, faculty perception.
- **Disruption awareness is not simply demoralizing.** Among 568 Chinese design students, awareness that AI may replace parts of design work was positively associated with self-rated innovation competence (β = 0.375), through a promotion-focus path of 0.0929 and a prevention-focus path of -0.0884 that nearly canceled each other (Wang et al. (2026)). Every measure came from a single self-report wave.
- **Disciplines differ in which behaviours pay off.** Shen (2026) compared 221 design students with 222 business students and found AI Literacy predicted both prompting proficiency and verification behavior (p < .001). Verification directly predicted task quality in the design cohort, calibration accuracy in business — open-ended ideation against audit-like analytic standards — and verification functioned as a metacognitive safeguard against Cognitive Offloading.
- **Studio judgement can be approximated when a rubric mediates.** Yaşar et al. (2026) raised LLM–human agreement on 80 design posters from 54.75% to 81.25% by iteratively refining rubric descriptors; instructor, peer-reviewer and grant-reviewer prompts produced epistemically different feedback on the same work. The authors treat the rubric as a revisable interface between pedagogical intent and machine inference, retaining human oversight against hallucinated rationale.
- **Students negotiate the tools rather than simply accept them.** Liu, Meng & Zhang (2026) surveyed 417 art and design students: performance expectancy, social influence, novelty value and creative competence predicted intention to use text-to-image tools, while effort expectancy predicted negatively, read as shortcut-oriented coursework use. Their competence paradox is that creative competence supports intention yet predicts more selective use as students weigh authorship and skill preservation — an Assessment Validity problem in a studio where process is the assessed object. Rana et al. (2025) reached a compatible conclusion from 112 reflections in a

12-week Design Thinking course: benefits dominated (86% positive sentiment), ethical concerns drove 62% negative sentiment, and scaffolded integration moved students from skepticism to 72% positive orientation.

- **GenAI can assist a workflow while weakening creative self-belief.** In a 36-student architectural design experiment, a DALL-E 3 workflow matched precedent search on rated performance and cognitive load, yet general creative Self-Efficacy fell (DiD = −0.543) while task-specific confidence held (Xiao et al., 2026).
- **AI critique can be bound to the artifact rather than the prompt.** Kadir (2026) routes studio feedback through a shared board of designs, notes and pins and five bounded activities; the study reports simulated readiness (78% of 109 labels at Analyzing or above), not learning gains.
- **A process rubric can make AI verification the graded object.** Orhon et al. (2026) propose the Merit Report, a four-criterion rubric (documented curatorial will 20%, tectonic translation 20%, rule-based technical validation 40%, peer audit 20%) that grades a student's documented AI-verification process rather than the artifact's polish, underwritten by a TPACK extension they call AI-Validation Knowledge.

Professional formation and regulation

Assessment problems here are inseparable from professional ones. Syed Abdul Rahman (2026) describes Malaysian interior designers shifting from primary form-generators toward critical mediators and curators of machine output, with Visualization platforms compressing timelines while generated schemes still lack cultural specificity, climatic responsiveness and reliable constructability. Its curriculum recommendation is sequencing rather than substitution — CAD/BIM, construction knowledge and human factors before generative exploration, and criteria rewarding Critical Thinking and ethical reflection. The professional side is unresolved: interior design regulation is less formalized than architecture's, leaving open questions of disclosure, accountability for algorithmic error, and deskilling among early-career practitioners. The analysis is document-based and single-country.

Common Misconceptions

- **"AI in a design studio is mainly a writing aid."** A survey of **280 Politecnico di Milano design students** plus **100 Masters AI-use journals** found use clustered in research and writing — **editing writing 77.5%, finding information 74.5%, brainstorming 68.0%** — with **whole-assignment use rare at 18.6%**. The pattern is augmentation of parts, not replacement of the whole, and the numbers show where the actual practice sits.
- **"Design students are enthusiastic adopters."** The same cohort shows **71% using GenAI daily or weekly, 65% distrusting it, and 85% modifying its output**. Frequent use and low trust coexist, so a tool whose value proposition assumes trust has misread the users.
- **"GenAI is generically helpful across the design process."** The GAI-A platform built across a longitudinal studio study found **two productive uses only**: GenAI as visual stimulus in early ideation, and as a **combinatorial expander of the solution space during development**. Usefulness was phase-specific.

- **“Creativity gains are too diffuse to measure.”** In a **31-student subgroup**, creative-thinking scores rose from **77.23 to 94.68 (d = 0.82)**. The gain is measurable and it is bounded to a subgroup, which is the honest form of the claim.

Medical and Health Professions Education

> **Medical and Health Professions Education (HPE)** — the teaching and training of medical, nursing, pharmacy, and allied health professionals. AI is reshaping this domain through clinical Simulation, reinforcement learning trainers, adaptive learning, and the application of foundational learning principles (experiential, situated, and distributed cognition) in health-professions contexts. Because HPE is high-stakes, competency-based, and clinically embedded, it raises distinct questions about AI's role in skill acquisition, patient safety, and the educator's judgment. Nursing, the most heavily studied program in HPE, now has a page of its own — Nursing Education — where the competence boundary, identity-formation, and workforce evidence that this page carries only in outline is developed in full.

Questions to Consider

- In medicine, AI benefits like scalable practice and adaptive feedback must be balanced against risks like erosion of hands-on clinical skill — where errors carry direct patient consequences. Where would you draw the line between what AI should do and what a trainee must practice for themselves?
- The page argues AI should be used to operationalize age-old learning principles — experiential, situated, distributed cognition — rather than replace the educator's guiding role. What makes the educator's judgment indispensable even when AI can simulate or personalize the practice?
- Reinforcement-learning trainers and agentic AI are now used for clinical and procedural skills in residency. If an AI agent trains a resident on a procedure, how would you verify they've actually learned it safely before they do it on a patient?
- Because health-professions education is high-stakes and competency-based, assessment questions carry particular weight. How might AI-assisted assessment both improve and threaten the evaluation of clinical competence?
- Over-reliance on AI is a specific concern in medicine. How do you think training with AI could produce a clinician who is more confident but less able to reason independently — and what could guard against that?

Introduction

AI in medical and health-professions education is a growing strand of the knowledge base's subject-area coverage. Unlike general higher education, HPE is oriented toward the development of clinical competencies, procedural skills, and professional judgment, which shapes how AI tools are designed and evaluated.

How AI appears in health-professions education

- **Operationalizing foundational learning principles.** Fowlin et al. (developed at the Medical University of South Carolina) argue that AI should be used to operationalize age-old learning principles — Dewey's experiential learning, situated cognition, and distributed cognition — rather than replace the educator's guiding role. AI enhances personalized and adaptive learning while the teacher remains central to student engagement and outcomes.
- **Clinical skills and reinforcement learning.** ResidencyRL uses reinforcement learning to train clinical reasoning and procedural skills in residency, demonstrating AI as a skills-training partner in real clinical workflows.
- **Simulation and agentic AI.** Agentic AI simulation in brachytherapy shows how AI agents support hands-on procedural training in medical specialties.
- **Gamification of medical learning.** MedGame applies gamification and LLMs to engage medical students.
- **Nursing and interdisciplinary education.** AI transformation of nursing education documents how AI reshapes nursing curricula and instruction. This page keeps nursing as one program among medicine, pharmacy, dentistry, and allied health, organized around the shared problem of scalable clinical competence; the nursing-specific record — a competence boundary where AI's documented benefits stop, an explicitly professional-identity framing, and students' workforce anxiety — belongs to Nursing Education and is cross-referenced here rather than restated.
- **AI-powered simulation in nursing.** Jiang et al. (2026)'s mixed-methods systematic review of 19 studies (N = 1,253) finds AI-driven simulations (GenAI/LLMs, virtual patients/mannequins, AI-enhanced VR/MR, and chatbots) significantly improve cognitive knowledge and affective outcomes (Self-Efficacy, communication confidence) in the strongest designs, but are inconsistent for complex psychomotor skills — one RCT found AI-assisted simulation *inferior* to standardized patients. Their concept of an **"authenticity gap"** — a learner-perceived shortfall in emotional resonance, nonverbal cues, and tactile examination — grounds why AI is best for highly structured objectives (foundational communication, history-taking) and should sit in a **stepped simulation continuum** alongside, not instead of, human-standardized patients and clinical placement. This is a distinctive, evidence-anchored refinement of the domain's Simulation strand and parallels the acceptance-trust finding that learners favor human feedback perceived as "benevolent" over AI seen as merely "competent."
- **LLMs and the reconstitution of professional identity in nursing (2026).** Sun et al. (2026)'s critical integrative review of 489 studies across 47 countries (Whittemore & Knafl framework) shifts the question from what LLMs can do in nursing education to what their integration does to the *developmental processes* through which a nurse is formed. Framed through Benner's skill acquisition, cognitive load theory, automation bias, and Wenger's identity formation, they find the same technology both enhances and erodes competence depending on whether the displaced cognitive work is extraneous to, or constitutive of, the target competence — unstructured reliance produced measurable deficits in ethical reasoning and clinical judgment. Their **Professional Identity Tension Model** distinguishes LLM integration that supports professional formation from

integration that silently substitutes for it, and **Structural Empathy Suppression** reframes apparent AI "outperformance" on relational metrics as a symptom of systemic overwork rather than genuine AI empathy. An evidence gap map shows the highest-policy-consequence domains (professional identity, relational/ethical competency, long-term outcomes) rest on the thinnest rigorous evidence — a caution against confident deployment claims in nursing education.

- **Multi-agent AI standardized patients in clinical interview training.** In a 2026 randomized controlled trial with 95 analyzed medical students (Yang et al.), multi-agent AI standardized patient training raised final OSCE-aligned examination scores over a structured non-LLM progressive-disclosure control (71.8% vs. 55.6%; β = 16.4 percentage points; P = 3.30e-4) while leaving binary diagnostic accuracy statistically identical (84% vs. 86%; P = 1.000). The dissociation indicates that early clinical-training gains can surface first in consultation process quality — communication (mean 3.53 vs. 2.64 on a 1–5 OSCE scale; P = 4.50e-4), empathic expression (+31 percentage points on the "expressing empathy" checklist item), and selected history-taking behaviors — before any improvement in diagnostic endpoints, and that AI patients still need human raters and faculty for professionalism and readiness judgments.
- **Criterion-level scoring localizes what an AI patient cannot do.** Across three Korean OSCE cases, three of four backbones sat within 0.5 Likert points of an expert reference on comprehensibility, consistency and hallucination-freeness, yet weaknesses concentrated in clinical reasoning and patient education and in a Korean negative-form penalty on fluency (Yi, Park & Kim (2026)).
- **Integrating AI into a residency curriculum is a governance problem before it is a content problem (2026).** Bursic et al. interviewed twelve physicians who lead AI work in Canadian and US postgraduate medical education. The five barriers they name are structural rather than pedagogical: review cycles slower than tool release, faculty expertise thin beyond a few experts, AI Governance that has not caught up on privacy and data ownership, no national competency standards, and cultural resistance tied to professional identity (Bursic et al. (2026)). Their proposal is a modular core — AI literacy, critical appraisal, bias detection, human-AI metacognition, ethics — with specialty and local-tool content reviewed every six to twelve months. Where this page documents what AI can teach here, this strand documents whether a program can teach it at all.
- **Students default to treating an AI patient as a searchable database.** Voice-interviewing a genAI avatar in a PBL pilot, students asked closed-ended, efficiency-focused questions — one asking whether the AI was "just, like, a question base" — and the encounters ran 55–65 minutes versus 36–39 for the legacy module (Mool et al., 2026).
- **Initiative is a second axis beside task allocation.** Jin et al. (2026) randomized 79 medical and nursing students and graduates to a reactive agent that waits for prompts or a proactive one that drives sequenced questions, writing analytical pieces over visuals built from the Multimodal AI traces of a four-person nursing simulation (a bar chart of time per behavior, a communication network, a ward heatmap). The two conditions differed sharply in epistemic structure (Cliff's delta of -0.56 and -0.78) while final scores did not, so where a tool sits in an allocation and how much initiative it demands are separate design decisions.

- **Cross-program analytics without shared student records.** Kovor, Osei and Agyemang (2026) partitioned the Open University Learning Analytics Dataset into five program-discipline clients as health-professions analogues and found federated logistic regression kept 99.3-99.9% of centralized performance, so the obstacle to sharing a risk model across programs is organizational rather than statistical. The reason a pooled model fails is pedagogical heterogeneity: their illustration has a nursing program at 30-35% at-risk against 15-18% for a concurrent medicine program, and forum activity ranked last as a predictor in every discipline because peer learning in these programs happens in clinical placements.
- **Task allocation and the SCAN framework.** Tsim et al. reframe AI integration from learner "misuse" to *misclassification* — a failure of real-time metacognitive evaluation. Their SCAN framework (Substitute, Complement, Aid, Non-Negotiable), grounded in Vygotsky's zone of proximal development, allocates generative AI tasks by the individual learner's developmental state and identifies passive engagement within AI-scaffolded tasks as a hidden pathway to mis-skilling that requires re-identification from AI to expert assistance with human epistemic auditors.
- **Human-in-the-loop instructional asset generation.** Gen-Mentor (Dong et al. 2026) integrates a vision-language-model backbone into a dental-radiography workflow: Faster R-CNN localizes four target findings (Filling, Implant, Impacted Tooth, Cavity), a conditional diffusion model generates class-specific synthetic ROI candidates, a VLM produces evidence-linked captions, and an Large Language Models (LLMs) reformats them into case descriptions, comparisons, and quiz prompts — all before structured expert review. Evaluated with 45 dental students (mean SUS 72.7), it demonstrates how human-in-the-loop review of AI-generated instructional assets can expand case diversity and immediate-feedback support while retaining expert oversight over what students see.
- **AI grading of pharmacy exams.** Falahat, Das, Bhaumik & Thambi (2026) evaluated ChatGPT-5 against human faculty grading of a 21-item pharmacy exam (16 students) across multiple-choice, select-all-that-apply, fill-in-the-blank, listing, short-answer, and essay items. The model matched faculty closely on objective items (CCC 0.935–1.000) but was unreliable for listing, short-answer (CCC ≈0), and essay (0.341–0.854) responses, and a structured rubric did not consistently improve agreement — evidence that in high-stakes, competency-based Assessment in health professions, AI suits well-specified items while human review remains necessary for subjective, open-ended clinical reasoning.
- **A validated LLM judge for clinical communication.** Hasan et al. (2026) scored the 3E communication skills from transcripts alone with a judge that reached Pearson 0.759 and ICC(A,1) 0.746 against the consensus of human raters, inside the spread of individual humans, though its weakest dimension (Be Explicit) did not improve across encounters.
- **GenAI in scenario-based healthcare education.** Neto and colleagues (2026) systematically reviewed 23 studies of GenAI across scenario-, case-, problem-, and simulation-based learning in healthcare education (PRISMA 2020). Their central finding is that **prompt design functions as instructional specification** — encoding the cognitive targets and quality criteria implicit in expert authoring — yet only 34.8% of studies aligned generated content with instructional frameworks and only 34.8% reported prompting in enough detail to reproduce. GPT-4 dominated

implementations (44.4%), hybrid human-AI collaboration outperformed fully automated approaches, and evidence was strongest for higher-order cognitive skills but inconsistent elsewhere. This grounds scenario/simulation-based and problem-based Pedagogies and Teaching Strategies in medical education with validation- and integration-quality benchmarks.

- **AI scoring of open-ended exam questions.** Olvet et al. (2026) tested whether GPT-4 could reliably score open-ended questions on pre-clerkship assessments at two US medical schools. With faculty iteratively refining scoring rubrics across three rounds of error-pattern analysis, AI–faculty inter-rater reliability reached substantial-to-almost-perfect agreement on three of four questions (weighted kappa up to 0.94) but only moderate on the holistic-rubric item (κw = 0.54); discrepancies traced to both raters (GPT-4 over-scoring multiple-answer or rubric-absent-vocabulary responses; faculty being overly generous) and occasional feedback inaccuracies keep humans in the loop. The authors argue the case for automated OEQ scoring is strengthened because ~82% of US medical schools grade pre-clerkship work pass/fail, where exact AI score agreement is not always required.
- **Repeated runs do not reproduce the same grade.** In a master's-level public health course, four general-purpose LLMs graded the same 32 anonymized essay submissions as two human examiners; ChatGPT in thinking mode reached weighted kappa 0.718, but regrading identical submissions on five different days reached only Krippendorff's alpha 0.625 (Brevik et al. (2026)). The authors advise averaging multiple assessments for high-stakes use.
- **Evaluating AI teaching agents, not just deploying them.** Zhang et al. (2026) deployed eight LLM teaching agents across four role-play paradigms (patient, student, expert, family member) in an endocrinology curriculum and scored 167 student dialogues with an 8-dimension teaching-quality rubric. Platform scores diverged sharply from rubric quality; agents differed most on knowledge dimensions and least on role enactment; adaptive difficulty calibration was a shared weakness; and strengthening an agent's empathy raised role-play quality without improving knowledge coverage. The finding that role-play paradigms can be separated (beyond the default patient-doctor script) points to designing and evaluating agents against explicit pedagogical dimensions.
- **The shape of the field's own literature.** Sriram, Nichols, Ganti and Gue (2026) map the ethical-AI-in-medical-education literature itself: 1,403 Web of Science publications from 1995 to 2026, negligible for two decades, then 113 in 2023, 256 in 2024 and 500 in 2025; 39 countries clear the authorship threshold, led by the United States (533 publications) over China (189) and England (95); and the most-cited works are capability tests — ChatGPT's performance on medical licensing examinations above all — rather than governance scholarship. Their reading is that the field has grown fast without growing evenly, and that empirical evaluation of AI Governance frameworks is the work the citation record is not rewarding. It is a useful caution for anyone treating the volume of published AI-in-medical-education research as evidence that its safe-use questions have been answered.

A 153-report scoping review of GenAI in medical education maps applications — Simulation and clinical skills largest (47 reports), ahead of assessment generation and feedback (22) and case-based learning and

clinical reasoning (21) — yet only 13 reports carried a follow-up or retention signal and no patient-level outcome was found (Zhao et al. (2026)).

Why it matters

HPE is a high-stakes, competency-based domain where AI's benefits (scalable practice, adaptive feedback, simulation) must be balanced against risks (Over-Reliance, erosion of hands-on clinical skill, ethical and safety concerns). The knowledge base's general concepts — Teaching, Assessment, Feedback, Equity, and Ethics — apply with particular intensity in health professions, where errors carry direct patient consequences.

Wang and Shan (2026) name the resulting "safety gap" — the divergence between a student's AI-assisted performance and their unassisted ability to verify it — and prescribe withholding solutions, constructive cognitive friction, and Socratic or Adversarial AI architectures for high-stakes clinical training.

- **What the curricula teach about data provenance.** Giancotti et al. (2026) coded the publicly advertised curricula of 36 U.S. health AI programs and found ethics covered in 29 (80.6%) but data provenance at a structural or dataset-limitation level in only 8 (22.2%), with no program addressing the environmental cost of computation and none of the seven master's degrees meeting the provenance threshold. Of 92 named instructors, 76.1% came from computational disciplines and 3.3% from the social sciences or humanities. The gap is clinically consequential: the deployment failures the paper opens with were introduced upstream, in how training data were generated or labeled, which is a teachable competency the curriculum appears not to carry.
- **Use has outrun instruction.** Among 310 health science students, 90% had used ChatGPT while 82.6% had received no formal AI instruction; usage frequency tracked higher GPA, and 61% reported ethical concerns (Alshahrani et al., 2026).

Implications for health-professions educators

- **Use AI to operationalize learning principles, not replace the educator.** Fowlin et al. argue AI should operationalize experiential, situated, and distributed-cognition learning while the teacher remains central to engagement and outcomes.
- **Leverage AI for clinical skills training.** ResidencyRL and agentic simulation show AI as a skills-training partner in real clinical workflows — embed it where it adds safe, scalable practice.
- **Balance high-stakes benefits against over-reliance.** HPE is competency-based and high-stakes; guard against AI substituting for hands-on clinical skill and judgment, and apply Feedback, Assessment, and Ethics considerations with particular care.
- **Adapt gamified and interdisciplinary AI thoughtfully.** Gamified LLM learning and nursing-education transformation show promise but need evaluation for safety and skill outcomes; for nursing specifically, that safety-and-skill evidence — including the RCT in which AI-assisted simulation underperformed standardized patients — is gathered on Nursing Education.
- **Order the curriculum by the evidence, not by the tools on hand.** The same KAS map shows where the evidence is thick and thin: ethics knowledge (14 studies), responsibility (14), application skills (16) and evaluation skills (18) carry consensus, while technical knowledge,

application knowledge and operational skills sit at 9 each and collaboration at 7. Where infrastructure is unreliable, reach the technical layer through screen-based cases and open-access model demonstration rather than waiting for high-fidelity simulation.

Common Misconceptions

- **“Simulation benefits are established in medical education, so AI simulation will too.”** A mixed-methods systematic review of **19 studies (N = 1,253)** finds AI-driven simulations produce effects in that literature — a modest base, and 1,253 participants across 19 studies is a narrow foundation for a technology being deployed at scale.
- **“The question is what LLMs can do in clinical training.”** A critical integrative review of **489 studies across 47 countries** shifts the question **from what LLMs can do to** what they should be trusted with. The capability question is largely answered; the governance question is not.
- **“Standardized patients are too costly to scale.”** A **randomized controlled trial with 95 analyzed medical students** used **multi-agent AI standardized patients** in clinical interview training. The constraint being addressed is the availability of trained human actors, which is a staffing problem rather than a fidelity one.
- **“Adopting a published AI competency framework settles the curriculum question.”** Xiang et al. (2026) screened 1,750 records to 23 studies — 15 reviews, 4 qualitative and 4 quantitative, across 15 countries and 2022 to 2026 — and mapped them onto the Knowledge, Attitude and Skill model. Application domains concentrated in medical education (n = 11, 47.8%), general education (n = 9, 39.1%) and other education (n = 3, 13.0%), and the named nursing frameworks they compared — N.U.R.S.E.S., AI-ABCs and CARE — either lack clear pathways for pedagogical implementation or cover isolated skills without assessment methods. The 12-sub-dimension map they build is a proposal awaiting validation, which makes it something to teach against rather than a settled curriculum.

Nursing Education

> **Nursing Education** — the preparation of nurses for licensed practice, and the subfield of health-professions education where AI is currently most studied. AI enters nursing curricula through Simulation with virtual patients and mannequins, LLM-based study and clinical-reasoning support, automated assessment, and adaptive platforms for at-risk learners. Its object is distinctive: nursing competence fuses psychomotor skill, relational practice, and professional identity formation, so a technology that raises measured performance can simultaneously erode the developmental work that produces a nurse.

Questions to Consider

- AI-supported simulation reliably improves knowledge and Self-Efficacy but shows inconsistent, sometimes negative effects on complex psychomotor skill. Where is AI the right teacher, and where must a human body in the room remain non-negotiable?
- Nursing students describe AI as emotional comfort during clinical stress. Is that a support to design for, or a signal that the relational apprenticeship is under-resourced?
- AI anxiety among health-sciences students tracks job-search anxiety. Is teaching AI literacy the remedy, or does it raise the salience of a threat that institutional policy should address instead?
- A nursing AI curriculum can be ordered by what the literature discusses or by what the clinical setting can support. When infrastructure is unreliable, should a program teach ethics and evaluation deeply and reach operational skill through low-cost simulation, rather than wait for the tools?

Introduction

Nursing education is the clinical strand of the knowledge base with the densest empirical record: system-wide reviews of AI applications, a mixed-methods synthesis of AI-powered simulation, a qualitative study of student and faculty experience, and a critical integrative review of LLM research sit alongside one another. That makes nursing a useful test case for claims the wider AI in education field makes about clinical training.

It must be kept distinct from Medical and Health Professions Education, which treats nursing as one program among medicine, pharmacy, dentistry, and allied health and organizes its account around the shared problem of scalable clinical competence. The nursing literature adds three things that page cannot carry: a competence boundary at which AI's documented benefits stop; an explicitly *professional-identity* framing, in which the question is who becomes a nurse rather than what a trainee can do; and a workforce layer — students' anxiety about AI displacing nursing roles, and the faculty view of nurses as shapers rather than recipients of healthcare's digital transformation.

The field also refines three adjacent concepts. From Simulation it inherits the fidelity debate but renames the deficit an "authenticity gap." From Affective Computing it takes the measurement of affect, yet its strongest

claim is that affective outcomes improve while emotional depth in the interaction does not. From Self-Efficacy it takes the central mediating variable, while cautioning that confidence built in a low-risk setting may not transfer to the clinical one. Beneath all of it sits the ordinary higher education problem of workload, access, and assessment integrity, sharpened by licensure and patient consequence.

How AI appears in nursing education

- **Four application areas, recurring risks.** Alrazeeni et al. (2026) reviewed 28 empirical studies (2010–April 2025) and group AI applications into personalized learning, simulation-based training, Automated Assessment, and institutional curriculum management with predictive analytics. Technological inequity, faculty preparedness gaps, and privacy and bias concerns recur. Their recommendations are concrete — embed AI simulation in emergency-care training, deploy adaptive platforms for at-risk learners, use automated tools for real-time formative Feedback, adopt diagnostic accuracy as the impact measure — within 6–12 month multi-site pilots tracking learning outcomes and trust.
- **Simulation: strong on knowledge and confidence, conditional on skill.** Jiang et al. (2026)'s PRISMA-guided mixed-methods review of 19 studies (N = 1,253, mostly prelicensure students) covers generative AI/LLMs, AI-driven virtual patients and mannequins, AI-enhanced VR/mixed reality, and chatbots. The strongest designs — three RCTs plus controlled quasi-experiments — show significant gains in cognitive knowledge and affective outcomes including Self-Efficacy and communication confidence, but effects on complex psychomotor skills are inconsistent, and one RCT found AI-assisted simulation *inferior* to standardized-patient simulation. Qualitative meta-aggregation explains both the appeal and the limit: learners value safe, repeatable, nonjudgmental practice that bridges the theory–practice gap, but report an **authenticity gap** — robotic dialogue, missing nonverbal cues, no tactile examination — plus technical instability that raises extraneous cognitive load and state anxiety. The authors recommend a stepped continuum: AI for pre-learning, history-taking, and foundational reasoning; human simulators and standardized patients for complex psychomotor and emotionally loaded work; human-facilitated debriefing alongside AI feedback.
- **Acceptance is real, and relational.** Akbaba and Calik Kus (2026) interviewed 28 participants (16 students, 12 faculty) and analyzed transcripts deductively through the Technology Acceptance Model. TAM held: ease of use, usefulness, intention, and use shaped adoption. The role split is practical — students used AI for presentations, visual content, clinical case analysis, and care planning; faculty for course materials, literature review, academic writing, and administration — implying tailored rather than uniform training. Two findings extend TAM's cognitive frame. Participants described AI as psychosocial support, a "companion" offering reassurance and a confidential space to reflect during clinical stress. And where AI *scored higher than nurses* on empathy in a high-volume context, Sun et al. (2026) read it as **Structural Empathy Suppression**: overwork makes authentic empathic expression unsustainable, algorithmic consistency fills the gap, and identity-constituting significance transfers to the algorithm — reframing the policy question from "how effective is this tool?" to "what conditions made it appear necessary?"
- **The open secret: practice outruns policy.** Ghimire and Qiu (2025) interviewed 17 final-year students at one Australian school, 10 domestic and 7 international, and found use normalized

while institutions discouraged it: “The biggest irony is that everyone knows we’re using AI” (SN9). Students used it for personalized learning, to bridge theory and practice and to manage time, and international students used it for language and cultural adaptation as well. Their themes name the digital divide and student-driven demand for curriculum change, which recasts adoption as a gap between what students already do and what the program admits to.

- **Faculty read the risk as professional, not procedural.** Dabkowski et al. (2026) interviewed 22 nursing academics across Australia and New Zealand and found them navigating policy that was absent, late, or written without them, sharply divergent collegial attitudes, and a line drawn at *replacement* rather than use. The objection was developmental before it was procedural: generating answers for a deteriorating-patient scenario means the reasoning is never practiced, and participants warned of a future cohort not fit for practice. Their summary was blunt: “Copilot won’t teach you to be a nurse.” Assessment practice was already moving toward invigilated exams, oral vivas and process evidence, and misconduct was read as a rehearsal for unsafe clinical shortcuts. That reframes Academic Integrity as a question about who is safe to practice rather than a compliance process. The academics asked for nursing-specific guidance tied to the profession’s ethical codes, GenAI literacy embedded across the curriculum, and staff development with unit co-design — not blanket prohibition.
- **Anxiety as a workforce signal.** Dağ et al. (2026) surveyed 821 health-sciences students (nursing among them) and found a moderate positive correlation between AI anxiety and job-search anxiety ($r = 0.233$, $p < 0.001$), with AI anxiety a significant predictor after controlling for socio-demographics ($\beta = 0.234$, $p < 0.001$). AI anxiety, they argue, is not a technology attitude but a psychological factor shaping how students see their professional futures — pointing to AI Literacy and career counseling, not tooling, as the intervention.
- **Groupthink and interprofessional teams.** Wiss et al. (2025) placed a generative AI agent (CALIE) into twelve newly formed interprofessional teams across seven health-professions programs, including nursing, during a 180-minute virtual problem-based learning session, prompting it to inject controversial viewpoints. Of 165 learners, 158 completed the survey; the agent was rated most useful as a tool ($M = 3.49$), then for feedback helpfulness ($M = 3.21$), and least as part of the team ($M = 2.88$), all pairwise differences significant ($F(2, 156) = 26.01$, $p < .001$). Facilitator stance mattered, and learners who rejected the agent’s responses still used them as a socially permissible way to speak up — disagreement with the AI did team work.

What the curriculum should cover, and where the map is thin

- **A twelve-part competency map, built because none existed for nursing.** Xiang et al. (2026) screened 1,750 records from PubMed, Embase, Web of Science and CNKI down to 23 included studies (2022 to 2026, 15 countries, 15 of them reviews). They mapped those studies onto the Knowledge, Attitude and Skill model, producing three dimensions and 12 sub-dimensions: foundational, technical, ethics and application knowledge; critical thinking, responsibility, ethical values, and openness and adaptability; and operational, application, collaborative and evaluation skills. They compared the existing nursing frameworks and found them untranslatable into curricula: N.U.R.S.E.S. covers roles, AI-ABCs covers objectives, CARE covers the prompt structure, and none supplies a pedagogical pathway or assessment methods.

- **Attention clusters where the writing is easy.** Ethics knowledge (14 studies), responsibility (14), application skills (16) and evaluation skills (18) carry consensus; technical knowledge (9), application knowledge (9), operational skills (9) and collaboration (7) do not. That is the same boundary this page documents from outcome evidence, reached from the competency side: the field knows most about what to say about AI's ethics and least about the operational layer clinical safety depends on.
- **The remedy on offer is a sequencing rule for under-resourced programs.** Teach foundational and ethics knowledge before technical knowledge; critical thinking, responsibility and ethical values before openness and adaptability; evaluation and collaboration before complex operational skill. Reach the technical layer through Simulation, and where high-fidelity or virtual reality simulation is unaffordable, through screen-based cases with pre-recorded material, open-access model demonstration and guided work with public datasets. Offline substitutes are named explicitly, including case-based discussion and conceptual demonstration of AI workflows. The stated motive is equity: if curriculum order follows the distribution of infrastructure, the concentration of the research in the United States (5 studies) and China (3) turns from a bibliometric fact into a curriculum problem.
- **The quantitative anchors are imported evidence, not results of this review.** Ethics knowledge has been shown to predict AI integration (standardized coefficient 0.636, p below 0.001), and a positive perceptual future orientation to raise students' ethical values (0.308, p below 0.05). Evaluation carries the stronger clinical anchor: an AI system scored therapeutic communication with an intraclass correlation above 0.97, and a retrieval-augmented implementation reserved the final decision for the teacher's professional judgment.

Competence, identity, and the evidence gap

- **Displacement is the design variable.** Sun et al. (2026)'s critical integrative review of 489 studies across 47 countries reframes LLM research in nursing around one criterion: whether the cognitive and participatory work an LLM displaces is *extraneous to* or *constitutive of* the competence being developed. Displacing documentation and routine retrieval frees working memory; displacing a full reasoning chain, an ethical justification, or an individualized care plan removes the object of learning. The evidence is not hypothetical — students using ChatGPT as a sole resource scored significantly below textbook controls on ethical standards and clinical reasoning, and an AI-integrated curriculum produced higher scores alongside less individualized, weaker-logic care plans, a performance–learning dissociation. Their **Professional Identity Tension Model** formalizes this across task, competency, and identity layers: outcomes measured with a tool available may index fluent performance rather than durable capability, so programs should use delayed, no-tool post-tests and transfer tasks.
- **The evidence is inverted.** The same review's gap map finds no randomized or quasi-experimental study of professional identity or career development, only three of relational and ethical competency, and no follow-up beyond 12 months — while controlled evidence clusters in cognitive and technical outcomes.
- **Surveillance is documented as perception, not as improved conduct.** Harerimana et al. (2026) mapped Remote Proctoring in nursing assessment across six studies (1,567 students) and found

deterrence reported almost universally by proctored students (98–100% agreement in one graduate program), while the single comparative performance study found an in-person proctored cohort scoring significantly higher on a readiness exam than a remotely proctored one. Anxiety ran both ways — some students calmer at home and relieved of travel, others unable to concentrate while watched and fearful of wrongful accusation — and four of the six studies reported connectivity failure, one load shedding, making equitable access the operative constraint rather than exam security. The authors' position is that remote proctoring should be one instrument among several, governed by data-protection standards and paired with integrity-by-design and authentic assessment rather than treated as the default safeguard.

- **Readiness splits inside a single faculty.** Rony et al. (2025) gathered 14 semistructured interviews and three focus groups with 16 participants, 30 nurse educators in total, at three nursing colleges in Bangladesh. Read through Technological Pedagogical Content Knowledge (TPACK), the transcripts put the readiness gap inside a single staff rather than between institutions: "Some of my colleagues are naturals with technology, but I feel like I need extra help to keep up" (P3), against unreliable connectivity and training nobody had provided. Ethics surfaced as a governance worry more than a curriculum topic, with data custody the recurring question ("Who has access to it, and how is it being used?"), and algorithmic bias the second. A mandate to adopt AI without training and infrastructure reads, in this account, as an unfunded expectation rather than a readiness failure. A published letter replying to the study makes that case at the institutional level rather than the individual one (Bridging implementation gaps: The critical role of institutional ecosystems in AI integration for nursing education).
- **A wide review base is not a deep one.** El Arab et al. (2025) read 18 prior reviews and found them converging on the same three priorities: ethical and social implications, transformation of nursing education, and strategies for integration. The reviews underneath stay largely descriptive, and von Gerich et al. reported that 34 of 93 studies failed to address ethical considerations at all, so agreement at the top of the pyramid is agreement among summaries.
- **Initiative is a design variable, not a learner trait.** Jin et al. (2026) randomized 79 medical and nursing students and graduates to a reactive agent that waits for prompts or a proactive one that drives sequenced questions, working over visuals generated from a four-person ward simulation. Epistemic network analysis separated the conditions with large effects on how ideas connected (Cliff's delta of -0.56 and -0.78), yet final writing scores did not differ. Their **agency gap** names both failure modes at once: an agent that demands more initiative than a learner has, and one that over-directs a learner who no longer needs it.
- **Risk models calibrated on another discipline flag this one almost everywhere.** Kovor et al. (2026) examined privacy-preserving at-risk prediction across program-discipline partitions, and the authors' own illustration is that a nursing program might run 30-35% at-risk while a concurrent medicine program runs 15-18%. Federated logistic regression kept 99.3-99.9% of centralized performance, so the barrier to cross-program modeling is organizational rather than statistical, but the same spread means an imported threshold misfires. Their finding that forum activity ranked last in every discipline is attributed to clinical placements, where peer learning happens in person.

- **Student AI-use surveys report a correlation and call it a mechanism.** Li et al. (2026) surveyed 1,020 nursing students at one institution, 98.8% of whom already used generative AI for coursework, and found AI interaction associated with educational interaction (r = 0.378) with self-regulated learning the stronger predictor (beta = 0.520). The structural model is just-identified, so it reproduces the data by construction and cannot order the three variables, and the interaction scale counts frequency and a peer norm rather than what a student does with the model.
- **Boundary conditions.** The strands converge on the same restraint. AI is best evidenced for structured, repeatable objectives — foundational communication, history-taking, health education, knowledge acquisition — and least evidenced for complex psychomotor skill, emotionally loaded interaction, and long-term professional formation. Acceptance is consistently moderate to high, but acceptance of AI *feedback* is conditioned by trust: learners prefer human sources perceived as benevolent over AI perceived as merely competent. The reviews are also geographically narrow, dominated by uncontrolled designs and self-report, and — in the simulation review — show a near-uniform positive pattern that raises publication-bias concerns.

Common Misconceptions

"AI-supported simulation improves nursing competence across the board." The benefit stops at a documented boundary. AI-supported simulation reliably improves knowledge and Self-Efficacy but shows **inconsistent, sometimes negative effects on complex psychomotor skill** — and psychomotor competence is not a peripheral outcome in a profession defined by it. A program adopting simulation on the strength of knowledge gains has evidence for a different endpoint than the one licensure tests.

"The workforce anxiety around AI in nursing is really a skills gap, so AI literacy training is the remedy." The anxiety is about employment, not about competence. A survey of **821 health-sciences students** found a moderate positive correlation between AI anxiety and job-search anxiety (**$r = 0.233$, $p < 0.001$**), with AI anxiety a significant predictor after controls. Teaching literacy addresses the fear of not being able to use a tool; it does not address the fear of not having a job — and the literature's professional-identity framing, who becomes a nurse rather than what a trainee can do, is where that question belongs.

"Learners want AI agents as collaborators." They want them as tools. Of **165 learners (158 completing)**, the agent was rated most useful *as a tool* (**$M = 3.49$**), then for feedback helpfulness (**$M = 3.21$**), and least *as part of the team* (**$M = 2.88$**), with all pairwise differences significant (**$F(2, 156) = 26.01$, $p < .001$**). Design that positions an agent as a team member is running against learner preference, not ahead of it.

"Any simulation study generalises to clinical practice." The evidence base reviewed here — **19 studies, N = 1,253, mostly prelicensure students** — is largely classroom and laboratory based, and the translation from simulated competence to supervised practice is exactly the step an AI-assisted simulation does not by itself rehearse.

"AI competency for nursing means handling the tools, so training should start with them." The framework literature runs the other way. The dimensions the reviewers found consistently addressed are ethics knowledge, responsibility, application and evaluation skills; technical and operational use is where the field has least to say. A program that buys tool licenses first is building the thinnest-evidenced part of the map, and the named frameworks it might adopt instead of a curriculum, N.U.R.S.E.S., AI-ABCs and CARE, are precisely the ones without assessment methods.

Implications for Practice

For instructors

- Do not adopt AI simulation to develop complex psychomotor skill on the strength of knowledge and self-efficacy gains. Keep deliberate supervised practice for the psychomotor endpoints and use AI where its evidence is strongest.
- Address employment anxiety directly rather than routing it through AI literacy modules; the correlation with job-search anxiety says the concern is about the profession's future, not the learner's tool fluency.
- Position agents as tools and feedback sources, which matches both learner preference and the design that produced the stronger ratings.

For faculty developers

- Treat readiness as a distribution and target the lower end of it, since a mandate without training and connectivity support reproduces the gap it is meant to close.
- Co-design the analytics with the people they describe: in one published case, nursing faculty and students built an AI-powered learning analytics dashboard together while educators kept responsibility for the judgments it informed (AI as Co-Designer and Feedback Partner: Enhancing Human Judgment).

For developers

- Report psychomotor and knowledge outcomes separately, since they diverge in this literature.
- Design for the tool and feedback roles first; agent-as-team-member framing is not what learners asked for.

For researchers

- Report prelicensure and practicing-nurse samples separately, and study the transition to supervised practice if the competence claim is to mean anything clinically.

Legal Education

> **Legal Education** — the professional preparation of lawyers, and the discipline in which generative AI raises the strongest version of the question every program faces: whether assisted performance on law-school tasks is evidence of the analysis the license depends on. Its structure is unusual. In the United States, AI Governance of the curriculum runs through ABA accreditation and a licensure examination rather than a ministry syllabus; teaching leans on the case method and Socratic dialogue, which depend on students arriving having done the preparatory reading themselves; clinics and legal writing courses carry the experiential weight; and the professional conduct rules students will be bound by already apply to the tools they are being taught to use. AI enters through legal research platforms, drafting support, hypothetical generation, and bar preparation, and its signature failure is not a wrong grade but a fabricated citation.

Questions to Consider

- If a student briefs cases with an AI assistant but cannot reproduce the reasoning unaided, what has the Socratic classroom been assessing all along — the preparation or the tool that produced it?
- Law schools are being asked to govern AI while the profession they feed is still deciding what lawful AI-assisted practice looks like. Should legal education follow the bar, or lead it?
- Legal education has more policy documents than empirical studies on this question. Is a discipline that teaches evidence law unusually well placed to demand better evidence about its own AI adoption?

Introduction

Legal education prepares students for a licensed profession with its own rules of conduct, its own accreditation body, and its own gatekeeping examination, which makes it the discipline in the knowledge base where education policy, professional AI Regulation in Education and assessment validity intersect most tightly. It sits alongside Medical and Health Professions Education and Nursing Education as a Workplace Learning discipline rather than a school subject, but its distinguishing feature is procedural: much of what law schools must decide is not *how* to teach with AI but *what the professional ethics rules require* of a graduate who will practice with it.

The evidence base is currently thin and policy-heavy. One substantial article anchors the page: Gutowski and Hurley (2025) surveyed and compared institutional generative AI policies across ABA-approved US law schools and proposed a governance framework. That imbalance is itself a finding, and the page flags it rather than papering over it.

Experimental evidence is beginning to arrive: Xie et al. (2026) randomized 84 law undergraduates to a GenAI-authored mystery role-play game or to the same instructor's lecture, and the game group scored far higher on a knowledge-and-reasoning post-test (partial $\eta^2 = 0.566$).

How AI appears in legal education

- **Legal research.** Commercial platforms such as Lexis+ AI and Westlaw Precision with CoCounsel embed generative features in the tools students are already trained on, which makes "AI use" hard to separate from ordinary database searching. Gutowski and Hurley note how much of the familiar workflow this compresses: identifying authorities and secondary sources in minutes instead of hours.
- **Drafting and writing support.** Initial case briefs, outlines, memoranda, first-pass syntheses and sentence-level feedback on clarity and grammar. The authors place AI-generated work in the same supervisory relationship as work by a paralegal or junior associate: a lawyer remains responsible for its accuracy and legal sufficiency.
- **Study and bar preparation.** Generating practice questions, fact patterns, and "hypotheticals" for timed practice, and tutoring on recurring weaknesses. Gutowski and Hurley pair this with the observation that generative AI now passes both the Bar Exam and the Multistate Professional Responsibility Exam, which they read as saying more about the minimal-competency bar than about the model.
- **Task-specific profiles, not a leaderboard.** Under a blind protocol, the same out-of-the-box models that reached human bar-exam levels (cumulative scores 26–79 of 100) all failed the notary exam, which requires goal-directed legal planning under strict formal constraints — and were misled by deliberate traps embedded in it (Bertoli et al. (2026)).
- **Journals, moot court and advising.** Screening submissions, preparing advocacy, and academic support programs using custom models trained on past exams, model answers and course materials.
- **Assessment and integrity.** The recurring problem cases: undisclosed drafting, citation to non-existent authority, and exams that no longer measure unaided analysis.

What the policy evidence shows

Gutowski and Hurley assess policies on five dimensions with 0–5 rubrics: **prohibitiveness**, **permissiveness**, **educational integration**, **transparency and accountability**, and **depth**. Their canvass found that most law schools adopted generally prohibitive stances, often explained as buying time to study the technology, while almost all policies reserved discretion to individual instructors. The permissiveness and prohibitiveness ratings correlated inversely, as expected, and the authors report no single accepted approach: policies range from comprehensive governance to no stated policy at all.

They also document how thin the sector's evidence is. The ABA's 2024 AI and legal education survey drew responses from only 29 schools, roughly 15% of ABA-approved law schools, so it can hardly be treated as representative; and a LexisNexis survey of 800 law students found only 9% reporting current use of generative AI for their studies, with 25% planning to adopt it. The authors read low reported use partly as a response to unclear rules, since clarity reduces the fear of breaking them.

Two further points shape their recommendations:

- **Faculty governance is a law-school-specific complication.** Law faculties, individually and collectively, hold unusually direct authority over curriculum and course standards, so policy has to be built with them rather than announced to them.
- **Clinical education raises a pedagogical objection, not a technical one.** Citing Karr and Schultz, they report the position that AI tools designed to mimic human responses do not develop the original judgment, client interaction and ethical decision-making that clinics exist to produce, and therefore should not be used in clinical courses at all.

The recommendations are procedural: clear and comprehensive guidelines whatever the institutional stance, full stakeholder involvement in drafting, proactive training for students and faculty, flexible governance reviewed periodically, and self-regulation through information sharing rather than waiting for the ABA to dictate policy.

Why the discipline is distinctive

Three things make legal education more than one more subject area.

Assessment validity is inseparable from professional competence. Over-reliance during law school is feared to leave graduates underprepared for work that demands independent legal analysis and advocacy, and grading that rewards fluent output cannot distinguish a student's comprehension from a model's. The validity question is therefore not academic.

In a legal-context experiment, 186 lay decision-makers on tribunal civil cases deferred to an incorrect AI position far less when the system withheld its own position (5.7–8.2% versus 42.0–60.5%), yet built no measurable judgment — protective rather than corrective, and measured in lay decision-makers, not law students (Tuo et al., 2026).

Disclosure norms are unsettled and consequential. Gutowski and Hurley report disagreement about whether any use of AI must be disclosed, proposals for student disclosure forms, and no consensus on citation practice, with the Bluebook still silent on citing generative AI. They also predict that disclosure requirements will eventually look as pointless as noting that a student used a search engine, which is a prediction about the shelf life of the rules now being written.

Professional ethics travel with the graduate. The ABA's duty of technological competence and its guidance on confidentiality, supervision and candour toward the tribunal apply to practicing lawyers using these tools, and law schools inherit the job of teaching them. That is why the discipline connects directly to the knowledge base's work on AI use disclosure and on the legal issues and risks that arise when institutions govern AI badly.

Open Questions

- Does AI-assisted legal writing coursework still develop the analysis that licensure assumes, or does it train a fluency the bar exam cannot detect either?
- What happens to Socratic teaching if the preparatory reading is routinely delegated, and is the classroom's silence about it a measurement problem or a design one?

- Legal education produces the people who will litigate and regulate AI in education. Does that make it the natural place for the knowledge base's legal-risk work to be tested, or does it distort attention toward the law schools with the loudest policies?

Common Misconceptions

- **"Law schools have settled on a position."** Most adopted **generally prohibitive stances**, often explained as **buying time to study the technology**, while **almost all policies reserved discretion to individual instructors**. A prohibition with an instructor override is not a settled position, it is a deferral with a default.
- **"Survey evidence describes the field."** The **ABA's 2024 survey drew responses from only 29 schools, roughly 15% of ABA-approved law schools**, and a LexisNexis survey of **800** practitioners measures a different population. Neither can be treated as representative of legal education, and both get cited as though they were.
- **"Withholding an AI recommendation is neutral."** In a legal-context experiment, **186 lay decision-makers on tribunal civil cases deferred to an incorrect AI position far less when the system withheld its own position (5.7-8.2% versus 42.0-60.5%)**. Withholding did not produce neutrality; it produced a large reduction in deference, which is an effect in its own right.

Information Technology Education

> **Information Technology Education** — the branch of computing education that prepares practitioners to select, deploy, secure, administer, and govern the socio-technical systems organizations actually run, rather than to study computation as a discipline in its own right. Its closest neighbor, and the source of most boundary confusion, is CS Education: computer science education centers on algorithms, programming, and formal foundations, whereas IT education centers on applied configuration, cybersecurity, data and information management, and the organizational AI Governance of those systems. Generative AI reaches the field twice over — as an object students must learn to evaluate, secure, and regulate, and as an instrument that tutors them, classifies their questions, and quietly rewrites the professional pathways they are being prepared for.

Questions to Consider

- If AI compresses the build-fail-debug cycles that historically produced IT expertise, which foundational competencies should a curriculum deliberately protect, and which can be delegated to the tool?
- Students know their institution's rules and still cannot say whether their own use complies. Is that a communication failure, or is a rule-based instrument the wrong lever for a practice that happens privately on personal accounts?
- IT education sits between computer science, business, and vocational education. Who should own AI governance competence — a course, a curriculum thread, or a program-level outcome?
- If a transformer classifier separates higher-order learner questions at roughly 79% precision, should IT programs automate formative feedback on questioning at all?
- Most student mental models of GenAI are declarative and shallow. Does that predict misuse, or only an inability to explain decisions students are in fact making correctly?

Introduction

Information technology education is the applied wing of computing. It trains people to make systems work inside organizations — networks, databases, security operations, health information management, e-government services — and its graduates are usually assessed by professional bodies and employers rather than only by the academy. The distinctiveness relative to CS Education is the unit of analysis. CS education takes the program and the algorithm as its objects; IT education takes the deployed system and the practitioner's judgment about it. Where CS debates whether AI code generation erodes programming skill, IT debates whether AI troubleshooting erodes diagnostic skill, whether AI-drafted policy documents bind anyone, and whether graduates can govern the data systems they administer.

The neighboring disciplines overlap in different ways. STEM Education is the parent category and shares its instruments, but IT education is more often a professional master's or an applied undergraduate degree whose graduates enter regulated workplaces. Business Education is adjacent through information systems and e-government programs, which frequently share courses and students with IT curricula. Vocational

Education and Training is the other occupational neighbor: both fields train for practice, but vocational programs target technician-level competence in defined trades, while IT education assumes abstract systems reasoning and produces the people who write the governance documents as well as follow them. Higher Education names the level rather than the field, and the field carries an accreditation and compliance surface — health informatics accreditation, HIPAA and FERPA obligations for the data students handle — that shapes what counts as legitimate curriculum.

What is distinctive about AI in this field is that the same technology is both the curriculum content and the Pedagogies and Teaching Strategies. The bundled evidence converges on one uncomfortable theme: IT education's current AI agenda is dominated by integrity and tool adoption, while the governance, security, and data-ethics competencies the field's own workplaces demand appear mostly outside the documents students actually receive.

How AI appears in Information Technology Education

- **Gamified cybersecurity training.** Li and colleagues built several short, mobile-friendly games spanning password security through text and phone scam recognition, combining quiz-based, narrative-based, and Simulation-based designs with interactive formats such as TikTok Mini-Games, motivated by the low engagement and limited effectiveness of conventional video training (Security Education in Higher Education through AI-Powered Gamification). Their two-tier evaluation with 59 college students (9 technical experts, 50 general users) reports potential to improve engagement and attention to cybersecurity rather than demonstrated learning gains.
- **GenAI as scaffold or shortcut in self-regulated learning.** A mixed-methods study of 267 postgraduate IT students in Australia distinguishes scaffolded Cognitive Offloading (learners clarify goals, generate ideas, obtain Feedback they then critique and adapt, so Learner Agency stays with them) from substitutional offloading (outputs accepted with minimal verification, control shifting to the tool) (Scaffold or Shortcut? Postgraduate IT Students' Use of Generative AI and Self-Regulated Learning). Confidence shaped orientation: confident students exercised autonomy in goal setting and monitoring, while less confident peers read GenAI as a shortcut or as misconduct. The cohort was differentiated, not homogeneously AI-literate; the authors recommend requiring students to justify or adapt AI outputs as an explicit Learning Design move.
- **Compressed expertise pathways in professional practice.** Fourteen semi-structured interviews with IT professionals found GenAI acting as both a mentor-like tutor and a ladder-shortening tool in troubleshooting, scripting, and system verification (Unanticipated effects of generative AI on expertise pathways and performance perception in system administration). Accelerated unfamiliar-domain performance reduces exposure to the build-fail-debug cycles that historically built expertise; AI-assisted speed also resets team and self-expectations, producing a two-speed culture and productivity guilt. The study carries classroom concerns about metacognitive cost and skill decay into Workplace Learning and workplace learning.

Assessment and the learner side of IT AI use

- **Learner questions as diagnostic signals.** Lee, Atif, and Kang classified 434 authentic student queries from 12 IT courses into three Constructivism instructional roles — knowledge transmitter,

facilitator, and co-learner — reaching consensus labeling with human-in-the-loop review (Fleiss' kappa 0.60 rising to 0.83) and augmenting the corpus to 582 balanced questions (Analysing AI utilisation in education through learner question types: A constructivist approach). The per-class results were uneven: DeBERTa scored 86.36% accuracy and 96.67% precision on factual questions, facilitator precision slid to 78.79%, and a fine-tuned BERT showed 92.00% recall but only 74.19% precision on co-learner items. Errors came from conceptual similarity between roles, ambiguous learner intent, and domain phrasing misread as cognitive depth; the authors warn that augmentation may have introduced lexical shortcuts, and the 11-student, IT-only corpus cannot yet generalize to other fields.

- **Wide but shallow mental models.** From 64 usable concept maps drawn from 86 undergraduates in a required technology-ethics course, five mental-model categories emerged: technical-process based, educational-tool based, transitional, consequence-aware, and integrated (Uncovering Students' Mental Models of Generative Artificial Intelligence). Every map showed declarative knowledge, 25 showed procedural, 17 conditional, and only 9 integrated all three. Technical and social-regulatory clusters sat far apart, which the authors read as AI Literacy and ethical awareness developing separately; integrity-centered guidelines, they argue, address only one dimension of how students conceptualize the tool.
- **Rules known, compliance uncertain.** A survey of 151 undergraduates in Business Information Systems and E-Government programs found most students actively using GenAI but over half unsure whether their usage complied with institutional regulation, with only weak to moderate associations between regulatory awareness and actual behavior, and reliance mostly on privately accessed tools rather than institutional ones (Knowing the Rules Is Not Enough: Student Regulatory Awareness and Use of GenAI in Higher Education). Knowing the rules did not strongly predict what students did.

Institutional policy and the governance gap

- **Guidance, not policy.** An environmental scan of all 48 accredited health informatics and health information management master's programs found 40 (83%) with at least one publicly available AI document, but the modal artifact was advisory guidance (21, 53%) rather than formal policy (7, 18%) (Institutional approaches to artificial intelligence policy and guidance in health informatics and information management education: emerging trends and inconsistencies). Academic integrity dominated the vocabulary (n = 139), ahead of citation (n = 59) and Assessment (n = 50), while HIPAA (n = 5), FERPA (n = 11), equitable access (n = 2), and disclosure requirements (n = 1) were nearly absent, and electronic health records were not mentioned at all. Latent Dirichlet Allocation produced four themes around integrity, student GenAI use, university research tools, and ChatGPT engagement. Because only public documents were analyzed, the authors treat the absence of privacy and equity language as a finding about published guidance, not about institutional practice.
- **The equity blind spot.** Inclusion (n = 9), accessibility (n = 9), accommodations (n = 4), and equitable access (n = 2) appear at rates that cannot support any claim that Equity has been addressed, even though several programs require AI use in coursework. Together with the thin treatment of professional AI Governance competence, this is the clearest design task the bundle

leaves open: connecting integrity rules to the access, privacy, and data-governance provisions those graduates will be responsible for enforcing.

Common Misconceptions

“Information technology education is computer science education with more vendor tools.” The boundary is the object of study. Computer science education centers on algorithms, programming and formal foundations; IT education centers on applied configuration, cybersecurity, data and information management, and the organizational governance of socio-technical systems. The distinction changes what an AI tutor should be good at: an IT learner needs judgment about a deployed system’s failure modes, not a proof about a computation.

“A classifier accurate enough to identify question types is accurate enough to automate formative feedback.” Aggregate accuracy hides the per-class error that matters. In the comparison this page cites, DeBERTa led at **86.36% accuracy and 96.67% precision on factual questions**, but facilitator precision fell to **78.79%**; a fine-tuned BERT reached **92.00% recall on co-learner items at only 74.19% precision**. Automation would route roughly one in four of those to the wrong intervention — and the errors concentrate on the pedagogically interesting categories, not the easy ones.

“Most programmes having an AI document means AI governance is in place.” In an environmental scan of all **48 accredited** health informatics and health information management master’s programs, **40 (83%)** had at least one publicly available AI document — but the finding is titled guidance, not policy. A published set of recommendations is not a governance mechanism: it neither assigns responsibility nor specifies what happens when a system fails.

“Students who cannot explain an AI-supported decision are misusing AI.” The alternative explanation is that they cannot articulate a decision they made correctly. IT work is full of competent practice whose rationale is tacit, and treating inarticulate competence as misconduct misdiagnoses a teaching target as a discipline problem — it needs explanation practice, not a policy.

Implications for Practice

For instructors

- Report per-class precision, not headline accuracy, before automating any feedback routing. The facilitator-precision figure is the one that determines how many students receive the wrong help.
- Teach explanation as a deliverable in its own right, so that inarticulate competence is distinguishable from misuse.
- Distinguish guidance from governance when reading institutional policy, and ask who is accountable when a tool in the pipeline errs.

For developers

- Publish confusion matrices by learner category; a model strong on factual questions and weak on co-learner contributions will systematically miss the collaborative cases.
- Do not position a routing classifier as a replacement for a facilitator. At 74-79% precision it is a triage aid.

For programme designers

- Build the governance artifact the sector is missing: named responsibility, review cadence, and an incident path. An AI guidance document satisfies an accreditation question and not an accountability one.

Libraries

> **Libraries** — the institutions that provide access to the scholarly and public record, and the operational systems behind that access: catalogues and discovery layers, reference and research services, collections, and the instruction programs that sit on top. In AI in education they matter twice over: as a setting where generative AI is being deployed in live services, and as the institution that carries information-literacy instruction while its own search layer is rebuilt underneath it.

Questions to Consider

- A reference desk once answered the factual question. When a chatbot answers it in seconds, what is the service for — and what should the staff who ran it be doing instead?
- The systematic reviews find AI adoption concentrated in reference and cataloguing while funding is the most-cited barrier. Is the binding constraint money, staff skill, or the absence of a decision about what the library is for?
- Library systems see the whole population a course-level tool never does: borrowers, non-borrowers, community members. Does that make the library the right place to host public AI access, or the wrong place to concentrate surveillance?
- AI literacy and information literacy are both taught by librarians and both lack a settled assessment. Should a library merge them into one program, or keep the frameworks distinct?

Introduction

The library is the part of the education system that has always been in the information-access business, which is why AI arrives there less as a novelty than as a change in the supply chain. Two literatures meet on this page. One studies libraries as adopters: what they are doing with AI, what stops them, and how the work is distributed across technical services, reference, collections, circulation, instruction and staff development. The other studies libraries as infrastructure: the place where students and the public meet search at all, and therefore where a shift from search to synthesis is first felt.

The page is deliberately distinct from Librarians, which covers the people and their professional role, and from Information and Media Literacy, which covers the construct they teach. This page is about the institution: its services, its systems, its staffing model and its public obligation.

How AI enters library operations

A systematic review of 29 studies published between 2020 and 2024 organizes AI adoption into six dimensions — technical services, reference and information services, administrative services and circulation, collection development, information literacy and user education, and professional development and collaboration — and finds the center of gravity in reference: AI for answering directional and ready-reference questions appears in 34.48% of the reviewed studies, with cataloguing and chat-transcribed reference next at 27.58% each (Ayinde, Ebiefung and Oladokun, 2026). The same review records what the

adoption literature usually softens: funding is named as a critical barrier in 48.28% of studies, technical skill gaps and poor data quality in 58.62%, and fear of job loss in 13.79%.

The distribution matters because it describes a library automating the parts of its work that were already transactional — the directional question, the catalogue record, the chat transcript — while the judgment-heavy work remains human. That is consistent with the instructional evidence elsewhere in the knowledge base: an embedded librarian consulted when a recommender was least confident handled mostly source-evaluation questions, not lookup questions (Huang, 2026).

The search layer moves

The library's discovery system is no longer the only route to the record. In a survey of 236 US university students, search engines remained dominant for academic retrieval, but generative AI had become a significant source, with younger and international students more likely to use it and heavy users more satisfied with the answers (Lund et al., 2026). Behavioral data complicate the self-report: at one Chinese university, nine years of loan records covering 3.2 million transactions showed no level or trend change at the January 2023 generative-AI breakpoint, even though a parallel survey of 368 students found substitutive AI use weakly associated with reduced intention to keep using print (Huang et al., 2026). The honest reading is that displacement is real in stated preference and uneven in behavior, which is exactly the kind of gap a library is positioned to measure and a course is not.

Instruction, staffing and the research base

Libraries carry AI instruction before they have a curriculum for it. A systematic review of 32 studies found integration running through LibGuides, tutorials, workshops and revised modules, with 30 of the 32 studies published in 2024 or 2025 and 11 from the United States (Mirza and Arif, 2026). A scientometric map of 1,669 publications in the same period shows the field's center of gravity in a small set of library journals, with the *Journal of Academic Librarianship* both the most productive outlet and the central node of the journal co-citation network (Jabeen and Lux, 2026). Neither map shows practice changing; both show a literature growing faster than the evidence of effect.

Staff capacity is the recurring constraint in the survey work: 412 academic librarians across 38 Nigerian institutions were studied for their student-engagement strategies in information literacy and AI instruction, and staff development recurs across reviews as the intervention libraries ask for (Dada, 2026). The operational question is not whether to train staff but whether the training is tied to a service the library has decided to run.

Public access as an AI question

The library's oldest function — providing access that individuals cannot buy — has acquired a new object. The Public AI Libraries pilot places a shared AI workstation in public libraries, gives each patron a separate account, and charges participating libraries $1,000 per kiosk per year. Whether or not the model spreads, it names the equity argument precisely: in a digital divide that now runs through AI capability, the library is the institution that can supply shared, staffed access rather than a subscription per person.

What this means for practice

- **Decide which services the library is running before buying tools.** The adoption literature is full of pilots without an owner; the reviews' most-cited barrier is funding, but the second is the absence of staff capacity matched to a service.
- **Keep a human escalation path in any AI service.** The evidence supports AI for lookup and drafting, and human staff for judgment about sources; designs that erase the second to scale the first remove the part patrons cannot get elsewhere.
- **Instrument the search shift rather than surveying it.** Loan and discovery logs already exist; a library that pairs them with instruction data will know more about AI's effect than a one-off student survey can show.
- **Do not bill AI literacy as information literacy.** They share staff and frameworks but differ in what is assessed; conflating them produces a program that measures neither.

Research fields

Learning Sciences

> **Learning sciences** — the interdisciplinary research field that studies how people learn and how to design environments in which learning happens, drawing on cognitive psychology, learning theory, computer science and linguistics, and judging its designs with empirical evidence rather than theory alone. In this knowledge base it is the research field around AI in education rather than one of the school subjects. It supplies the mechanisms that AI systems operationalize (knowledge components, mastery thresholds, transfer), the design objects they are embedded in (planned course sequences, tutors, Feedback regimes) and the standards by which they are judged (Learning Gains, Assessment Validity, equity). Its organizing question is not whether a tool performs well but whether a learner changed.

Questions to Consider

- A learner passes every practice item, so the mastery threshold ends the set — then misapplies the rule where the action should be withheld. Whose error is that: the learner's, the model's, or the stopping rule's?
- Sequence mining can describe 554 courses as patterns without observing a classroom. What does the field gain, and lose, by studying designed intentions instead of enacted activity?
- Demographic sensitivity in an LLM's feedback looks like adaptation when it tracks a learner's stated education level and like bias when it shifts sentiment. Should a field that cannot separate the two keep using open-ended models to assess?
- Does the learning sciences' appetite for causal design — randomized assignment, counterfactual audits, executable models of the learner — narrow what counts as evidence in AI in education?

Introduction

The learning sciences study learning and the design of learning environments, and they are defined by their methods as much as their topics: experiments, classroom trials, quantitative modeling of student data, qualitative analysis of designs and contexts, and design-based research that builds an intervention and revises it in use. That breadth separates this page from the neighbours that supply the frameworks, the practice and the instruments; the section below sets out each boundary and what the field has established on the other side of it.

This page covers the substantive knowledge such methods have produced — what learners do with a generative model, which arrangements change outcomes, and where the field's own instruments fail. AIEd in the Disciplines takes the opposite cut, holding that subject matter changes what support should do; the learning sciences take the cross-cutting view, and the mechanisms they test are gathered under Cognitive Psychology.

How AI appears in the learning sciences

- **Mechanism first, then the model.** An, McLaren and Stamper (2026) ran eleven experiments (N = 192) with Intelligent Tutoring systems for Riichi Mahjong and showed that learners who compiled an overgeneralised production — the action without its application constraint — misapplied it on the first "do-not-act" item at 61.5%–100%, against 12% expected error under Bayesian knowledge tracing. With a 95% mastery threshold the system stopped practice before learners met a case requiring the action to be withheld, so the defect went undetected. Short do-not-act practice with Feedback naming the missing constraint cut misapplication to 0.0%–23.1% (Cohen's h 1.70–2.44), and a secondary analysis of thirteen K-12 *Decimal Point* datasets found the same structure in whole-number bias (84%–88% of comparison errors).
- **A consensus maps where GenAI helps and harms learning.** A preregistered Delphi of 30 learning scientists rated 65 learning processes and agreed on 42: GenAI threatens initial acquisition and higher-order thinking but enhances consolidation (Kendeou et al., 2026).
- **Feedback style, not agent type, moved self-regulatory engagement.** In a 2 × 2 experiment with 51 postgraduate students, Socratic feedback was associated with stronger comprehension monitoring while directive feedback carried higher cognitive load; the two styles ran in a fixed, non-counterbalanced sequence, so the contrast is condition-related rather than causal (Han et al. (2026)).
- **The optimum depends on the content.** Rachatasumrit, Koedinger and Carvalho (2025) treat the example–problem ratio as a content–treatment interaction: in a 2×2 experiment with 95 participants on geometry-area material, practice-only training produced larger learning gains for verbatim facts while example-integrated training produced larger gains for generalizable skills ($\beta = 0.41$, $p = .038$, $d = 0.38$). A simulated learner (Apprentice Learner) reproduced the crossover only when given an ACT-R-style memory-and-forgetting mechanism. More practice is not uniformly better: memory-oriented content warrants retrieval, and induction-oriented skills warrant integrated examples.
- **Design as an analysable object.** Divjak, Svetec and Horvat (2026) turned Learning Analytics on Learning Design itself, coding 29,064 activities across 554 courses planned in a free course-design tool. Acquisition was the most common learning type and the most common entry point; the strongest Markov transition was Assessment → Discussion (0.332) and the highest-confidence rule was Acquisition → Assessment → Practice → Practice (0.743, lift 1.45). Learning type tracked intended outcome level, Acquisition falling from about 50% of activities at Bloom level 1 to around 20% at level 6. The authors stress these are pre-implementation designs: resemblance to flipped, inquiry-based or project-based sequences is not evidence of intent.
- **Auditing the models that assess.** Rooein, Benedetto and Hovy (2026) audited six LLMs across essay scoring, formative feedback and question answering, holding the task input fixed while varying only demographic context (192,480 calls). Scoring was stable under explicit personas, but Llama-70B inflated its own scores by 1.57 points under implicit conversational history ($p < 0.001$), and higher education drew less readable and more positive responses — a sentiment gap of roughly four standard deviations. Readability effects shrank while length effects grew, and some coefficients changed sign between conditions. The authors offer it as an audit instrument, not a

deployment verdict, and read the entanglement of demographic and topical signal as a threat to validity and equity.

- **Measuring competence, and its limits.** Verí (2026) organizes instruments for competent Generative AI use into four domains — knowledge and use, epistemic oversight, reliance calibration, and control of tool-using agents — refusing to collapse them into one proficiency continuum. Three same-sample correlations between self-rated and demonstrated AI literacy pooled to r = .055 (95% CI [-.047, .156], reported N = 2,765), which the author reads as enough to reject treating self-ratings as interchangeable with performance scores, though not enough to set a cutoff. No validated instrument covered the full set of decisions that tool-using agents create; the proposed layered battery is a design hypothesis.
- **Self-report about the learner's own offloading.** Alam (2026) translates the Cognitive Offloading literature into PAUSE, a browser-only self-check with four domains, every LLM-era item anchored to a source, no composite, no storage and no model in production; its bands are descriptive rather than normed, and a reading must not justify assessment, admissions or hiring decisions. Its stated limits matter: self-report of offloading is vulnerable to the faculty it concerns, a respondent who deliberately uses AI as a scaffold reads as offloading on several items, and whether AI-associated offloading is distinct from general technology dependence remains open.
- **Where human expertise sits.** Wang et al. (2024) report the clearest division of labor: in a two-month randomized controlled trial with about 900 novice K-12 tutors and roughly 1,800 students. Real-time suggestions drawn from experienced tutors' reasoning raised topic mastery by 4 percentage points (62% to 66%, $p < 0.01$), and by 9 points for lower-rated tutors, at about $20 per tutor per year. The suggestions shifted tutoring toward guiding questions. Gains were proximal — year-end tests did not move. Reichert et al. (2026) find teachers arriving at the same position by design: six secondary teachers prototyping chatbots specified a bounded expert, holding authority boundaries (responsibility for learning and safety is not delegable) and expertise boundaries (the model lacks their knowledge of individual students), and delegating content presentation, practice and corrective Feedback while reserving objective-setting and summative assessment.
- **Capability at the level of the field.** Sutedjo, Chowdhury and Liu (2026) surveyed 127 faculty with a TPACK instrument adapted for generative AI: strong content and pedagogical content knowledge (M = 4.70–5.15) beside markedly lower technology-integrated knowledge, with holistic TPACK lowest at 2.55, content knowledge uncorrelated with any technology-integrated domain, and the three integrated domains correlating so highly (r = .81–.91) that they may function as one factor. Perrotta (2026) reads the governance layer through a discontinued UK civil-service prototype whose codebase was a system prompt plus a retrieval pipeline over commercial models, arguing that the generality of foundation models both enables rapid repurposing into policy tools and makes aberrant output a permanently only-mitigable risk — oversight that peers over the loop rather than sitting inside it.
- **The integration gap, mapped:** Malik and Bashir (2026) synthesized 32 studies (PRISMA 2020, thematic analysis) into four themes: epistemological fragmentation within the field, theory–technology contradictions (computational systems run on prediction and measurable behavior while educational theories emphasize context and social interaction), the datafication of

learning through analytics, and hybrid intelligence as an emerging paradigm. Their Hybrid Intelligence Framework is a conceptual synthesis, not a validated model — the authors state it awaits empirical testing — but the four-theme map is a useful audit lens for the theory-to-computation translation problem this field keeps hitting.

- **How students use a generative model matters more than whether they do.** Coding 50 undergraduate exchanges found 64% were passive review or transactional questions and only 36% strategic dialogue, and a reflection-structured assignment shifted the balance toward dialogue (Zahra, 2026).
- **Within-person reliance precedes a drop in perceived Learner Agency.** Across three waves of data from 342 undergraduates in 85 fixed groups in an AI-supported collaborative writing course, higher-than-usual GenAI reliance predicted lower subsequent perceived human agency, while the reverse path was weaker and not statistically supported (Wu and Lu (2026)).
- **The distribution of GenAI use is an institutional choice.** Sun, Dohn and Rehm (2026) classified 102 higher-education studies by how epistemic work was distributed between student and system and found Assistant and Enabler entanglements dominating at 42.16% each, reading the skew as institutional legitimacy rather than technological capability.
- **Process evidence is channel-conditional.** Coding one GenAI-assisted instructional-design task with 79 undergraduates in both interaction logs and concurrent think-aloud, Li and Liu (2026) found higher-depth monitoring evidence more common in the think-aloud record but higher-depth AI Regulation in Education evidence more common in the logs, so neither trace alone is the criterion for a metacognitive claim.
- **The method matters as much as the finding: sequence analysis of group-AI interaction.** Wang et al. (2026) coded 595 and 785 utterances around 39 chatbot prompts, tested lag-1 transitions with adjusted residuals and Yule's Q, then ran process mining with each episode as a case. That pairing placed the AI at the center of one group composition's interaction network and on a single path in another, a difference that prompt tallies could not show. It is a template for asking where an AI sits in a group's interaction network rather than how often it appears.

How the learning sciences relate to their neighbours

Design-based research is the method this field developed rather than borrowed: an intervention is built and revised inside a working classroom, with its theoretical rationale revised alongside it, so one study yields both an artifact and a design principle. That is what separates it from a laboratory experiment, which isolates a cause by holding the context still, and it is why the field's findings arrive as design knowledge rather than as effect sizes. Research Methods in AIED takes the other cut: that page surveys the whole repertoire — experiments, surveys, qualitative work, benchmarks, reviews, consensus methods — as a choice among instruments, weighed for the validity of the claim each can support. This page reads the same corpus from the substantive side, asking what the repertoire has established about learning and judging a method by whether its design claim survives contact with learners.

Learning Theories collects the candidate frameworks — Behaviorism, cognitivism, constructivism, sociocultural accounts, motivation and self-regulation — as lenses for reading AI. The learning sciences

share that vocabulary but not that stance: here a theory is a claim about mechanism that a design must either instantiate or refute, and the field's standing rests on empirical and design work rather than on the coherence of a framework. The theory page is the one to open for what a framework asserts; this page is the one for the evidence a framework has accumulated.

The field also builds theory rather than only testing borrowed frameworks: Theory Development in AI in Education covers the conceptual work that explains how learners, teachers and AI systems interact, and it is where the field's own constructs are argued before they are measured. What its designs are usually asked to produce is transfer — knowledge and skill that survive past the tutor, subject or task they were learned in — which is why a gain measured inside a tool counts as a weaker claim than one measured without it. And because a designed environment is a compound intervention, attributing an outcome to one component is the field's standing measurement problem: Educational Measurement supplies the psychometric apparatus that makes the attribution arguable at all, which is why measurement questions arrive early here rather than after the fact.

Cognitive Psychology is the mechanism-level discipline the field draws on most heavily, supplying bounded working memory, encoding and retrieval, decomposable knowledge components and the diagnostic language of learner modeling. The learning sciences use those mechanisms without reducing to them: their unit of analysis is a designed environment carrying social, motivational and contextual variables that a laboratory account of memory does not, and their tests are run on whole interventions rather than on isolated cognitive effects.

Pedagogies and Teaching Strategies and Learning Design cover practice — which teaching strategy to use, and how to sequence objectives, activities and assessment into a course. Both are what the learning sciences study from the outside, as objects of description and evaluation; the field does not tell a teacher which tactic to reach for next, it reports what the tactics have been shown to do. Learning design is the closer relative, since both produce something that can be implemented and tested, but the designer's output is a teachable course and the field's output is knowledge about designs in general.

The findings only matter once they reach teaching, and that journey runs through three pages. Educational Development is the institutional practice that carries them — faculty development, standards, policy and identity work decide whether a validated design ever reaches a classroom, which is why the field's evidence routinely leads what institutions have implemented. Teacher Education is where the knowledge has to land before a teacher enters the room, and Teaching is where it lands afterwards, in the moment-to-moment judgment about when to intervene, which instrument to use, and when to leave a learner alone. None of the three produces learning-science findings; all three decide whether those findings change practice.

Common Misconceptions

- **"A high mastery threshold guarantees the learner can discriminate."** An, McLaren and Stamper (2026) ran **eleven experiments (N = 192)** with Intelligent Tutoring systems and found that at a **95% mastery threshold the system ended practice before any case required the learner to withhold the action**, so the defect went undetected. Mastery of the action did not include knowing when not to apply it, and the threshold certified the wrong construct.
- **"More examples are safer."** Rachatasumrit, Koedinger and Carvalho (2025) treat the example-problem ratio as a **content-treatment interaction**, and in a 2×2 experiment the optimum

depended on the content. There is no globally correct ratio, so a fixed instructional template is a bet against an interaction.

- **"Fixing the misconception is a matter of telling students the right answer."** Short do-not-act practice with Feedback naming the missing constraint cut misapplication to **0.0%-23.1% (Cohen's h 1.70-2.44)**, and a secondary analysis of **thirteen K-12 *Decimal Point* datasets** found the same structural pattern. The effective intervention was discriminating practice with targeted feedback, not correction by assertion — which is what refutation work establishes generally.
- **"Higher Bloom level means more active learning."** Acquisition dominated the lower levels — **about 50% of activities at Bloom level 1** — and shrank to **around 20% by level 6**. Cognitive demand and activity type move together but are not the same axis, so tagging a task by Bloom level does not tell you what learners will do with it.

What this means for practice

For instructors

- Teach the negative case explicitly. The 95%-threshold failure is the reason: build in conditions where the correct move is to withhold the action, or the learner will apply it everywhere.
- Do not fix the example-problem ratio across a course. The content-treatment interaction means the right ratio for procedures is not the right ratio for concepts.
- Use discriminating practice with feedback that names the missing constraint rather than restating the rule. That is the intervention with measured effect sizes here.
- Check what your mastery criterion actually certifies before you trust it.

For developers

- Do not stop practice on correctness alone. Model the withholding condition as its own skill, or the system will certify overgeneralisation.
- Let the ratio be a parameter rather than a constant, because the evidence says the optimum is content-dependent.
- Report which construct your criterion measures, separately from which construct your validation measures.

Levels and contexts

Levels and settings

K-12

> **K-12** — the use of artificial intelligence in primary and secondary education, spanning AI literacy curricula, AI tutoring, teacher support, and safety considerations unique to younger learners. A 2026 PRISMA-guided systematic review of 197 studies (2016–2024) organizes the field around four opportunity domains — personalization, motivation, Assessment, and innovative teaching practices — while flagging persistent gaps in teacher training, ministerial ethical guidelines, and discipline balance.

Questions to Consider

- K-12 AI use demands stronger safety protections than higher education because younger learners are least equipped to detect unsafe or manipulative AI. How does that change what ‘safe’ must mean for tools used by children?
- Systematic reviews find the K-12 evidence base concentrates overwhelmingly on STEM, leaving the arts and humanities largely unstudied. What might a discipline-balanced K-12 AI evidence base reveal that STEM-only studies miss?
- Research finds teachers systematically overestimate their AI competency — a roughly 40% gap between self-report and performance — yet short training yields substantially higher integration. What might that gap mean for how schools prepare teachers?
- Most AI tools center dominant perspectives, yet 78% of teachers in one study found AI helpful for culturally relevant pedagogy. How can a tool that defaults to dominant views be steered to broaden representation rather than narrow it?
- Evidence suggests outsourcing AI work can harm learning, especially for older students — yet younger students may be less affected. Why might the learning penalty of AI use differ by age, and what does that imply for design?
- The K-12 review identifies eight under-explored research gaps, from the missing concrete teaching-unit examples to the underuse of robotics, wearables, and mobile communication. Which of these gaps most limits what schools can actually do today?
- Institutional AI policies often lack implementation guidance. What would it take to turn a K-12 AI policy document into concrete classroom practices and teacher training — and why might that translation so often fail?

Introduction

The evidence landscape

A 2026 PRISMA-guided systematic review (Marzano, 197 studies, 2016–2024) now anchors the K-12 evidence base, complementing earlier large syntheses such as the rapid review of GenAI and PreK-12 learners and the aggregated K-12 AI evidence base. Its four-question structure organizes the field into four opportunity domains — personalizing learning, motivating students, improving assessment, and enabling

innovative, immersive teaching — with ChatGPT as the flagship case studied across a large share of the included articles.

The review's central finding is a sharp asymmetry: the *promise* of GAI in schools is broad and well documented, but the *evidence of daily classroom practice* is thin, concentrated in STEM, and skewed by a shortage of concrete teaching-unit examples and practical teacher training. This gap between aspiration and implementation is the defining feature of K-12 GenAI research.

A teacher-side synthesis adds the layer that tool-focused reviews leave out. A PRISMA review of 29 studies of teacher intervention in K-12 AI-based instruction finds that AI output — alerts, dashboards, automated scores, chatbot feedback — becomes teaching only through a cycle of monitoring, judgment, intervention and orchestration, and that the reported benefits for student performance, participation and confidence are conditional on the interpretability of the information, intervention timing, the level targeted, teachers' implementation feasibility and students' autonomy. Its corpus is concentrated in the same places as the wider K-12 evidence base: mathematics and science/STEM subjects, middle and high school grades, and United States settings.

Distinctive K-12 considerations

- **Safety and guardrailing:** K-12 AI use demands stronger Pedagogical Safety protections. EduZone, EduGuard, and tutor harm research specifically address child-safe AI interaction.
- **AI literacy curricula:** K-12 AI literacy modules develop age-appropriate AI understanding, while the vibe coding framework empowers teachers to create their own AI tools. A quasi-experimental study of an 18-hour, 5E-model critical media literacy program for fourth-grade Turkish students (Demir & Akar 2026) embedded generative AI (ChatGPT, Grammarly, Canva AI, Padlet) phase-by-phase as a pedagogical agent aligned to the Turkish Language and Social Studies curricula, producing large gains in media reading (+3.50), writing (+1.67), and total media literacy (+5.17, all $p < .01$) with between-group effect sizes of Cohen's $d = 1.12–1.31$, and qualitative growth across six domains of critical media literacy (digital self-protection and data privacy, purposeful and responsible media use, safe communication and boundary awareness, critical evaluation and misinformation awareness, online risk awareness, and media ethics/digital citizenship) — evidence that age-appropriate, discipline-embedded AI literacy curricula can yield measurable critical-media gains in the elementary grades.
- **Tutoring at grade level:** K-12 personalized companions and correct answer trap research examine tutoring effectiveness for younger students.
- **AI tutoring's constraint is engagement, not capability.** In 18 Tennessee middle schools, assignment to Khanmigo raised math achievement ~0.06–0.08 SD per school year — gains resembling Khan Academy practice without AI — because the median student messaged the tutor in only 17% of mistake sessions (Oreopoulos and Low, 2026).
- **Developmental appropriateness:** Child safety research and Special Education considerations address the needs of diverse K-12 populations.
- **Age-tailored conversational AI:** Vahedian Movahed & Martin (2025) deployed AMA, a topic-bounded chatbot with age-varied prompt tailoring, with 63 students (grades 1 and 6–8). Children showed broad openness to and high trust in the chatbot as an information source and actively

tested its credibility with known-answer questions, while gaps in digital-safety awareness (some were willing to confide secrets) point to age-sensitive Scaffolding and explicit Privacy instruction.

Teacher-knowledge effects

- **Teacher-knowledge effects.** A cross-level study (46 teachers, 2,832 secondary students) found pedagogical AI knowledge — not technical AI knowledge — drove students' perceptions of AI for social good and their intention to learn AI, reinforcing a "pedagogy first, technology second" approach to K-12 AI teacher preparation.
- **Continuous training as the binding constraint.** The Marzano review identifies continuous, targeted teacher training on ICT as the single most persistent integration challenge, and it must cover technical, pedagogical, and ethical dimensions while adapting to rapidly evolving tools. Initial and ongoing training should be continuous, collaborative, game-based, transparency-focused, and grounded in professional development for advanced tools like ChatGPT. This extends to classroom collaboration-support AI: the Community Builder (CoBi) feasibility study in middle-school classrooms found that high-integrity teacher use depended on substantial professional learning, with under-prepared teachers drifting toward treating the tool as a performance monitor or into general AI-discussion rather than its intended collaborative focus.
- **Unplugged Machine Learning literacy through familiar content.** In an online professional-development program, Sung and Gunpinar (2026) had ten K–12 educators build a visible yes/no feature matrix for classifying 2D shapes, so the algorithm could be inspected rather than accepted as a black box, and Self-Efficacy toward AI use rose from 3.13 to 3.71.
- **The competency gap.** Research shows teachers systematically overestimate their AI competency — a roughly 40% gap between self-report and performance — yet brief training interventions (e.g., 4-hour prompting workshops) can yield substantially higher classroom AI integration. This makes teacher preparation and Teacher Education central to successful K-12 AI integration.

Four opportunity domains

The systematic review consolidates what GAI can do in schools into four recurring domains:

- **Personalized learning.** GAI tailors learning experiences to individual needs, pace, and readiness — the flagship benefit documented across companion systems and adaptive platforms.
- **Readability and curriculum alignment.** Bird (2026) fuses transformer text classification with computational-linguistics features to classify English literature by UK Key Stage (F1 0.996), packaged into a no-code web app so teachers can align reading materials to learners' levels — a concrete, discipline-relevant (English/literature) complement to the STEM-heavy K-12 evidence base.
- **Motivation and engagement.** Tools like ChatGPT make learning more engaging for younger students, supporting engagement and Motivation — though the review also warns this can tip into excessive reliance and technological dependency.

A 42-study meta-analysis qualifies that: the motivational effect was smallest in school settings (secondary g = 0.360, primary g = 0.311) against g = 0.886 at university, though those subgroups rest on only 9 and 4

studies (Fang et al. (2026)). - **Assessment.** GAI improves Assessment methods, from formative Feedback to automated scoring, though bias in automated feedback remains a live concern. Razavi and Powers (2026) extend this to item calibration in K-5: across 5,170 math and reading items, GPT-4o's zero-shot difficulty ratings correlated moderately-to-strongly with Rasch-calibrated difficulties (r = 0.83 math, r = 0.81 reading) but were uneven across grades and no better than a grade-mean dummy regressor for grades K and 1 — a range-restriction limitation that matters for early-grade assessment. A feature-based approach (Large Language Models (LLMs)-extracted features into tree-based models) reached correlations up to r = 0.87, with gains most pronounced for early-grade items. - A related question is which model a school runs at all: on NGSS-aligned middle-school (1,078 items) and high-school (1,150 items) sets, nine open-weight models from six labs mostly scored above 90% and model size did not predict accuracy — OSS-20b and Nemotron 3 Nano 30b a3 matched models several times larger — while item difficulty ran high and discrimination low, leaving the authors to ask whether the Benchmark is too easy (Schroeder et al. 2026). - **Innovative teaching practices.** Immersive, game-based, and collaborative approaches make learning more engaging, with constructionist and project-based models showing particular promise. A concrete classroom-wide example is the Community Builder (CoBi), an AI collaboration-support system deployed across six middle-school classrooms that used speech recognition to visualize small-group "uplifting" discourse — evidence that real-time speech AI can work feasibly in noisy K-12 environments to support the relational dimension of learning.

Cultural relevance imperative

LLM-supported curriculum design shows promise for diversifying materials — in one study 78% of teachers found AI suggestions helpful for culturally relevant pedagogy. However, most AI tools center dominant perspectives, requiring deliberate equity-centered design to avoid widening opportunity gaps.

The caveat is that representation is not transformation: in an all-girls GenAI makerspace, girl-only grouping, women facilitators and feminine marketing acted only at the symbolic level, while cost barriers and English-only prompts persisted and only two of 44 generated images reflected the workshop's own climate-change topic (Liu et al. (2026)).

Policy-to-practice translation

Institutional GenAI policies largely lack implementation guidance. The systematic review underscores that ministerial guidelines addressing Ethics and Privacy remain underdeveloped, echoing the policy-to-practice translation problem: successful models transform policy documents into actionable teacher training modules, bridging the "what" (policy) and "how" (prompting instruction).

Scale and equity

K-12 AI deployment operates at societal scale — millions of students, compulsory education, and significant equity implications. Equity research examines whether AI widens or narrows opportunity gaps, including access and inclusive support for students with disabilities — one of the review's eight under-studied areas.

Raising the floor is not leveling the playing field: over a year of school AI instruction, 752 Hong Kong junior-secondary students gained confidence, motivation and ethical awareness, with low-agency late

learners approaching parity, while objective AI-literacy gaps persisted and self-initiated learning predicted the largest cognitive gains (Liang et al. (2026)).

Eight research gaps

An innovative contribution of the Marzano review is its explicit enumeration of eight under-explored research gaps that shape a K-12 GenAI research agenda: (1) a lack of concrete examples of AI in teaching for constructing teaching units; (2) a need for practical, daily teacher training based on constant AI application; (3) skills in machine learning and a balance between disciplines, with STEM over-represented; (4) a lack of studies and experiments in Europe; (5) a need to define the teacher role and create specific pedagogical frameworks such as Technological Pedagogical Content Knowledge (TPACK) or AI4K12; (6) inclusivity and support for students with disabilities; (7) a connection with pedagogical theories and innovative methodologies; and (8) applications of emerging technologies such as wearables, robot control, and mobile communication.

Connections

K-12 connects to Pedagogical Safety (child protection), AI Literacy (student competency), Teaching (K-12 teacher transformation), Equity (access gaps), and Special Education (diverse learner needs). Its systematic-review evidence base links to Meta-Analysis and Systematic Review as a method, and its discipline-imbalance finding connects to STEM Education, Humanities and Social Science Education, and Early Childhood Education.

Implications for K-12 instructors

- **Prioritize child-safe guardrailing.** K-12 AI use demands stronger safety protections — use tools specifically built and vetted for children (EduZone, EduGuard) and be alert to the harms of unguarded tutors (tutor harm research).
- **Build AI literacy age-appropriately.** Use curricula and frameworks designed for younger learners (K-12 AI literacy modules), and don’t assume students arrive with responsible-use knowledge.
- **Close the teacher-competency gap.** Teachers systematically overestimate their AI competency (~40% gap between self-report and performance), yet short training (e.g., 4-hour prompting workshops) yields substantially higher classroom AI integration — invest in your own preparation (Teacher AI Competency, Teacher Education).
- **Keep training continuous and practice-grounded.** The systematic review’s core recommendation is that teacher training cannot be one-off — it must be continuous, collaborative, and based on constant daily AI application, not abstract theory.
- **Diversify materials deliberately.** AI is strong at culturally relevant material generation (78% of teachers find suggestions helpful), but tools default to dominant perspectives — actively use AI to broaden, not narrow, representation, and guard against opportunity gaps.

- **Watch the learning-penalty risk.** Evidence shows outsourcing AI work can harm learning, especially for older students (cognitive surrender, homework-outsourcing penalty) — design assignments that keep cognitive work in the loop and assess for durable understanding, not just completion.
- **Distinguish a productive slowdown from a streak.** A randomized field experiment with 6,000+ middle-school students found AI support slowed progress but raised next-attempt correctness after errors, while a three-correct-in-a-row rule lifted platform mastery by roughly 28.7 percentage points without improving a delayed test a week later (Oreopoulos et al. (2026)).
- **A disengaged turn is not a stable state.** Rho et al. (2026) coded 5,522 middle-school math utterances and found the highest-performing cluster recovered from mocking or wrong answers, while withholding was the one disengagement behavior that persisted rather than resolved.
- **Modeled prompts can become templates students copy.** Across two 120 min STEAM modules, twelve eighth-graders' GenAI logs were dominated by information requests (303 of 310) and exact copying of the instructor's instruction was their most frequent standpoint (47.1%), with evaluation and reflection at 0.5% of coded content and result verification never coded (Zhao and Li (2026)).
- **Design teacher tools for judgment, not volume.** More AI information is not better: real-time alerts expanded teachers' awareness but in some studies overloaded attention or pulled focus from their own observation, and a single teacher cannot act on more intervention targets than they can physically reach (Lee 2026). Tools that prioritize and explain what is worth acting on, and let teachers accept, revise, defer or reject recommendations, fit the work better than dashboards that surface everything — and the structural conditions (review time, class size, support personnel) are part of the intervention, not background logistics.
- **Extend beyond STEM.** The evidence base skews heavily toward STEM; educators and researchers in the arts and humanities have an outsized opportunity to generate the discipline-balanced evidence the field is missing.
- **Translate policy into practice.** Institutional GenAI policies often lack implementation guidance; turn policy into concrete, actionable classroom practices and training (policy-to-practice).

AI Adoption and Skepticism in K-12

- As AI enters schools, the staff it affects are increasingly urged to consult conversational AI about adoption. An algorithmic audit of ten frontier LLMs probed a rural K-12 AI-skeptic persona, finding eight of ten models acknowledged concerns before redirecting to AI-engagement framings — a model-dependent design outcome rather than an inevitable property of LLMs. Trust, skepticism, and human oversight are therefore central to how rural and other K-12 staff encounter AI.

Grade-band progression is asserted in these frameworks and tested in none of them. Kharbach et al. (2026) searched 339 records and included 50 K-12 AI literacy frameworks, and found no study that tracked the same students across more than one grade band. Sun and Chan's measurement invariance across

years 10 to 12 supports consistent scoring rather than developmental growth. A K-12 plan can sequence content across grades, but that sequence is a design proposal rather than an evidence claim.

Common Misconceptions

- **"Teachers know their own AI competence."** Teachers **systematically overestimate their AI competency** — a **roughly 40% distance** between what self-report claims and what measurement shows. Self-Assessment is not a usable needs-analysis instrument at this level of divergence.
- **"AI tools are culturally neutral in practice."** Most AI tools **center dominant perspectives**, yet **78% of teachers** in one study found AI **helpful for culturally relevant pedagogy**. Teachers are using these tools for a purpose the tools were not built to serve well.
- **"The K-12 evidence base is one literature."** A **PRISMA-guided systematic review of 197 studies (2016-2024)** organizes the field around **four opportunity domains**, which means findings under one domain are not evidence under another.
- **Compulsory-school students acquire AI practice before AI curriculum.** Bergdahl (2026) studied a Swedish school running an "AI on the schedule" pilot for **year 7 students**, in a country whose national curricula include AI training only from upper secondary upward. The instruction covered ethics, prompting, train-your-own-model, recommender systems and data collection across three phases — and still left **data privacy (Mdn = 1)** and **algorithmic manipulation (Mdn = 2)** the weakest registers, against governance at Mdn = 4. Where the curriculum is silent, a pilot can supply instruction; it does not thereby supply the outcome.

Connected FAQs

- How Should Parents and Teachers Approach AI with Children Under 13?

Early Childhood Education

> **Early childhood education** — the use of artificial intelligence in the education of young children, spanning preschool and the elementary (primary) years. This covers AI-literacy and computational thinking curricula for young learners, AI-enabled toys and play, personalized learning in elementary subjects, and the developmental, safety, and equity considerations unique to children rather than adolescents or adults.

Questions to Consider

- Young children now meet AI through toys, chatbots, and classroom robots. What makes a 5-year-old's relationship with AI fundamentally different from an adult's — and what should change about how we think about the risks?
- Some early-childhood AI literacy is taught through 'unplugged' play — no computers at all. How can abstract AI concepts be learned through embodied, tangible activities rather than screens?
- A concern called 'technological isomorphism' describes young students mimicking AI output without understanding. How would you distinguish a child who has genuinely learned from one who is simply parroting back a polished answer?
- Because young learners are more vulnerable and less able to self-regulate, adult Scaffolding becomes central. What does that mean for a parent or teacher deciding when and how a child should use AI?
- If access to AI-rich early learning — or to protective adult guidance — is uneven, how does equity show up differently in early childhood than it does for older students?
- The evidence base here is largely exploratory and design-oriented rather than causal. What would you want to know before trusting a claim about an AI toy or app improving children's learning?

Introduction

Young children interact with AI increasingly early — through AI-enabled toys, chatbots, adaptive learning platforms, and classroom robots — yet they differ developmentally from the K-12 and higher-education learners who dominate most AI-in-education research. This concept gathers the knowledge base's coverage of that younger band. It sits within the broader K-12 umbrella but is distinct because the concerns are developmentally specific: play as a primary learning mode, adult (parent/teacher) scaffolding, age-appropriate AI literacy, and heightened attention to Well-Being and safety.

How the research clusters

- **AI literacy through unplugged play.** The AI-Play framework teaches early-childhood AI concepts through *unplugged* (no-computer) activities, showing that abstract AI ideas can be introduced to young children through embodied, playful, and tangible activities (see Game-Based Learning) — a developmentally appropriate route into AI Literacy and Computational Thinking.

- **AI-enabled toys and child development.** Research on AI in toys examines how commercial AI-enabled playthings shape child development and play. This raises open questions about agents in play, trust calibration, Learner Agency, and Well-Being for the youngest learners — an area where design guidance is thinner than for school-age curricula, and where parents/guardians become central stakeholders.
- **Children's attitudes toward age-tailored chatbots.** Vahedian Movahed & Martin (2025) deployed "Ask Me Anything" (AMA), a topic-bounded chatbot (astronomy, sneakers and shoes, dinosaurs) tailored by age via prompt engineering, for 63 children (ages 6–14), revealing three patterns in child–AI interaction — wonder and curiosity, testing trust and building confidence, and building relationships through anthropomorphization — alongside a broad openness to and high trust in AI as an information source. Their call for age-sensitive design and explicit teaching of digital-safety and data-use concepts reinforces the developmental and safety concerns central to this concept.
- **Elementary subject learning.** AI-powered personalized learning in elementary fractions and AI in elementary math (including concerns about "technological isomorphism" — students mimicking AI output without understanding) show both the promise and the pitfalls of AI in early subject instruction. A systematic review of elementary writing and GenAI maps how generative AI is reshaping writing instruction in the early grades.
- **Primary English language learning has its own map.** A PRISMA-ScR review of 119 reports on AI-mediated tools in primary English sorted them into five pedagogical functions, and its strongest design, a cluster randomized trial with 217 second-grade learners, gained on taught words (effect size = .38) while standardized vocabulary and reading comprehension did not reach significance (Li and Zhou (2026)).
- **Robots and young children.** Robotics in kindergarten supports computational thinking through educational robots, and LLM-powered humanoid storytelling explores whether parents will accept robots as narrative play partners for their children — foregrounding Trust and adult attitudes.
- **Conversational agents as SEL facilitators, not substitutes.** Raave et al. (2026) had 18 educators and 18 agent simulations each lead three story-based social-emotional learning activities with a static AI child, giving 108 blind-coded observations: the agent was steadier on respectful tone and procedural scaffolding, while educators led on guiding reflection and social-emotional knowledge.
- **A competency set, not an AI-literacy curriculum.** A review of 86 resources argues AI literacy "cannot be standalone" for children aged 0 to 8 and nests it among executive functions, well-being, learning dispositions, and foundational skills, though only 26 of the 86 resources were empirical (Pei (2026)).
- **A "Creative Project Approach" pairs AI agents with classroom robots.** Yang, Li and Lee (2025) propose a five-step pedagogical framework that integrates generative AI agents and robots into the Project Approach to foster young children's creative learning. They argue physical agents are more appropriate than screens for young children. They pair two complementary paradigms with their learning theories — **coding robots** (Papert's constructionism; computational thinking through tangible programming with tools like Matatalab and KIBO) and **generative social robots** (Vygotskian scaffolding within the child's Zone of Proximal Development, acting as

conversational peers or tutors). The five steps — identify learning needs, facilitate teacher-guided child–robot interaction, situate AI in contexts, calibrate the automation/creativity balance, and evaluate outcomes — offer designers and ECE practitioners a concrete route for embedding AI agents and robots in play-based, project-based classrooms while preserving teacher facilitation and child Learner Agency.

- **Play-centered AI literacy curricula.** Lee (2026) reports the design-based research of Play With AI (PL-AI), a developmentally appropriate curriculum in which two pre-K and two kindergarten teachers co-designed seven sequenced activities blending unplugged play (composing and testing "how-to" algorithms), tangible coding (Bee-Bot, Ozobot), and guided dialogue with a social AI robot. Formative evidence showed substantial growth in teacher confidence and pedagogical agency, with four design principles emerging — **embodied play, tangible coding, guided dialogue, and teacher co-design** — aligned with the AI4K12 Initiative and NAEYC frameworks. This is a model of how robots and tangible tools can be embedded in play-based, teacher-led AI literacy for the youngest learners.
- **AI-assisted lesson planning for children's STEAM arts teachers.** An experimental study of children's art teachers (Luo and Tahir 2025) found ChatGPT-assisted lesson plans were rated significantly higher in quality than teacher-generated ones by six expert professors (median 20.5 vs. 17.6, $p = .002$, large effect), while mapping how teachers delegated — most often (60%) to fill content gaps in a self-outlined lesson rather than to generate whole plans. Teachers valued AI chiefly as an inspiration and gap-finding tool for interdisciplinary STEAM integration and faster topic selection, but flagged outputs that were impractical for real classrooms, overlooked child-safety constraints (e.g., carving knives for young children), and carried Western-centric cultural bias — concrete, developmentally grounded caution for generative AI use with young learners that a Role–Instructions–End Goal prompt framework was built to temper.
- **AI-supported critical media literacy in the elementary years.** Demir and Akar (2026) evaluate an 18-hour, 5E-model critical media literacy program for fourth-grade students in a Turkish public primary school, embedding generative AI (ChatGPT, Grammarly, Canva AI, Padlet) phase-by-phase as a pedagogical agent rather than an isolated add-on, with activities aligned to the Turkish Language and Social Studies curricula. The AI-supported group showed large gains in media reading (+3.50), writing (+1.67), and total media literacy (+5.17, all $p < .01$) with between-group effect sizes of Cohen's $d = 1.12–1.31$, while the control group advanced only modestly. Qualitative analysis of interviews, student artifacts (posters, drawings, slogans), and classroom observation surfaced six domains of critical media literacy growth — digital self-protection and data privacy, purposeful and responsible media use, safe communication and boundary awareness, critical evaluation and misinformation awareness, online risk awareness, and media Ethics/digital citizenship — offering a rare quasi-experimental, curriculum-aligned model of how AI can support critical AI literacy and critical thinking in the elementary grades.
- **AI-rated observation of teacher–child interaction quality.** Fong et al. (2026) benchmark an Large Language Models (LLMs) against trained human raters on the full CLASS Pre-K framework in Hong Kong kindergartens — 87 video-recorded observations from 38 classrooms across 30 kindergartens, rated from transcripts by GPT-5.0 and compared with eight trained raters. Agreement was moderate overall (weighted $\kappa = 0.681$) but conditional on the construct:

convergence held for the Emotional Support domain and for Quality of Feedback — the dimension carried by explicit, exchange-based verbal support — while Classroom Organization diverged entirely and raters rated the emotional dimensions higher than the model did, at a very large gap on the reverse-scored Negative Climate dimension (d = 2.732; raters gave the maximum of 7 in 63 of 71 observations, AI clustered at 6). The early-childhood lesson is developmentally specific: quality that lives in nonverbal, spatial and routine behavior — management, movement, warmth, tone — is invisible to a transcript-only pipeline, the model's error direction is construct-dependent rather than uniformly conservative, and the authors therefore position AI scoring as a screening and reflection tool for teachers rather than a substitute for trained observers.

- **Preservice educators designing science activities.** Efthimiou & Plakitsi (2026) had 131 preservice early-childhood educators design magnetism activities with LLMs: they rated the models' structure and efficiency highest (M = 3.95) but the epistemic trustworthiness of their content lowest (M = 3.08), treating them as brainstorming artifacts while keeping didactic transformation a human responsibility.
- **What predicts whether preschool teachers adopt AI at all.** A survey of 270 preschool teachers in Shanghai, Zhejiang and Guangdong, modeled with an extended TAM, found perceived usefulness and ease of use predicted intention to use AI, with AI Self-Efficacy raising it and AI anxiety lowering it (Duan, Shan and Gong 2026). The study excluded child-facing tools by design, so its levers — confidence-building and low-stakes training — concern teachers' own professional work.
- **AI approximating developmental judgments of children's stories.** Yin et al. (2026)'s CLARA annotates a story's cognitive, language, and social-emotional demands and matches publisher age references 0.904 of the time, ahead of readability formulas (0.603) and direct prompting (0.730) - offered as a supportive signal, not a replacement for a human judge.

Developmental and equity considerations

Because young learners are more vulnerable and less able to self-regulate their use of AI, this cluster emphasizes **scaffolding by adults** (parents, guardians, and teachers), **age-appropriate design**, and the risk of over-reliance and harm if AI substitutes for, rather than supports, the developmental work of play, discovery, and effortful learning. Equity is a live concern: access to AI-rich early learning (or to protective adult guidance) is uneven, connecting to Digital Divide and Equity. Much of the evidence base remains exploratory or design-oriented rather than causal.

A four-country comparison sharpens the curriculum gap: Japan, South Korea and China's national early childhood guidelines contain no explicit AI literacy references (Shanghai's city-level action plan is the lone exception, specifying no learning progressions), while Australia shows only limited, uneven alignment — strongest in interacting with AI agents, absent in understanding human-AI relationships — leaving AI literacy to the home (Cohrssen et al. (2026)).

A first neuroimaging window on this question arrives with a caution: 6–7-year-olds holding a five-minute spoken conversation with ChatGPT in an MRI scanner showed weaker within-network connectivity than adults in the frontoparietal control, salience and dorsal attention networks, at matched creativity scores, and lacked the creativity–connectivity coupling adults showed. Because those executive functions are still

immature at first grade, the authors read the result as relevant to the minimum-age debate — while flagging a framing confound and the absence of a no-ChatGPT control as limits on what it settles (Horowitz-Kraus et al. (2026)).

Common Misconceptions

- **“Teachers will use AI to generate whole lessons.”** Teachers delegated most often (**60%**) **to fill content gaps in a self-outlined lesson** rather than to generate whole plans. The unit of delegation is the gap, not the lesson.
- **“Young children gain less from AI-supported media literacy.”** The AI-supported group showed **large gains in media reading (+3.50), writing (+1.67) and total media literacy (+5.17, all p < .01)** with between-group effect sizes d = 1.12 or higher. The gains were large in this age band, not marginal.
- **“Automated observation agrees with human raters across the board.”** Agreement was **moderate overall (weighted κ = 0.681) but conditional on the construct**: convergence held for the **Emotional Support** domain and for **Quality of Feedback**, and not elsewhere. Averaging over the domains hides where the instrument fails.

Connected FAQs

- How Should Parents and Teachers Approach AI with Children Under 13?

Higher Education

> **Higher Education** — the integration of artificial intelligence into university teaching, learning, assessment, and administration. Higher education is the most-studied context in the knowledge base, with over 100 articles examining how AI transforms college-level instruction, institutional policy, and student experience. AI in higher education is both the dominant setting for AIED research and the site where its tensions are most visible — between generative AI's promise of scalable personalization and its risks to integrity, learning, Privacy, and equity. It encompasses both undergraduate and graduate study, including professional programs such as medicine and business.

Questions to Consider

- Higher education is where AI's tensions are most visible — scalable personalization versus risks to integrity, learning, privacy, and equity. Which of these tensions do you see playing out most concretely in your own institution?
- Large studies reveal gaps between institutional policy and what students actually do with AI day to day. Why do you think official policy so often diverges from real student practice?
- The page frames AI adoption as uneven — some institutions transform while others lag, shaped by organizational drivers and national policy. What factors do you think determine whether a university adapts or stalls?
- As AI makes personalized one-on-one support nearly free and universal, how does that shift the value and role of the university itself? What becomes scarcer and therefore more valuable?
- One finding notes a decline in study time among college students using AI. If students spend less time studying but report satisfaction, what does that suggest about what institutions should be measuring and guarding?
- Given the gap between faculty self-assessed and actual AI readiness, what would meaningful faculty development look like in your context — and who should be responsible for it?

Introduction

AI in higher education research spans every function of the university: from AI tutoring and automated grading to faculty development, academic integrity, institutional governance, and student support. The knowledge base's higher education articles cluster around several key themes — institutional transformation, student experience at scale, faculty and teaching, assessment and integrity, and the rapid shift in policy and practice. Across the review's 394 GenAI higher-education studies, participant focus was students in 352, instructors in 15, both in 26, and multiple stakeholder groups in 1 — so the evidence base for perceptions and teaching practice is overwhelmingly student-based (Lin et al. (2026)).

Institutional transformation

Institutional change frameworks analyze how universities adapt to AI — not just at the classroom level but across policy, governance, and organizational structure. The EPIQ-AI framework reframes faculty readiness as a sociotechnical alignment challenge involving epistemic, pedagogical, institutional, and quality domains. Rethinking universities in the AI era examines whether current institutional models can accommodate AI-driven education. Adoption is not uniform: organizational-driver research identifies what enables or blocks institutional uptake, and national policy analyses show how systemic context shapes university responses. A concrete institutional blueprint comes from Qin (2026), who documents Lingnan University's repositioning as a "Research-Intensive Liberal Arts Institution in the Digital Era," mandating GenAI literacy for all undergraduates and embedding digital literacy across the Common Core while developing a human-in-the-loop model that foregrounds ethical reasoning and critical judgment — arguing the AI-for-education shift is an intellectual transformation, not technocentric augmentation. Macro-level mapping of 22 higher-education AI-integration interventions (AlSheikh et al., 2026) reinforces that transformation remains more aspiration than reality: graded on the SAMR model, most interventions sit at Substitution or Augmentation, integration is concentrated in medicine, engineering, and computer science with little humanities presence, and evidence skews to North America and Asia with minimal Global South representation.

A global comparative index measures the discourse–structure gap. Chan (2026) coded the official websites of all 100 Times Higher Education 2026-ranked universities against a 20-indicator AI Institutionalization Index. The symbolic layer is saturated while the structural layer is thin: 100% have an AI task force and a master's AI degree, but only 12% have executive AI leadership, 5% require an introductory AI course for undergraduates, and 0% publish an AI accessibility policy despite 93% deploying AI campus services.

Institutionalization also proved independent of prestige (rank correlation $r \approx 0.04$), with significant regional variation (ANOVA $F = 5.86$, $p < .001$; North America $M = 0.63$ vs. Europe 0.51, Asia 0.50) and a six-model typology in which only a small subset of mostly large US publics reach "deep institutionalization." The author flags the index as a first-generation, unvalidated, website-only measure of the elite top 100 — a comparative map, not a scorecard.

Which forms of GenAI use an institution has made legitimate is itself measurable. Sun, Dohn and Rehm (2026) classified 102 empirical higher-education studies by how epistemic work was distributed between student and system, and found Assistant (42.16%) and Enabler (42.16%) applications dominating while Generator, Reimaginator and Synthesizer together made up under a fifth of the corpus — not because the models cannot do the rest, but because the marginal forms distribute authorship in ways the university's individual-competence logic does not yet recognize. On their account the binding constraint on GenAI in higher education is institutional legitimacy rather than technical capability, which puts the question squarely in the same policy and assessment-redesign territory as integrity and Assessment reform.

Ranieri and Biagini (2026) tested the 2019 four-category higher-education taxonomy against 228 publications from 2019–2026 and found 58.4% of the 154 classifiable applications fall outside it, adding AI-enabled student support, content and instructional design, and institutional analytics as functional domains.

AI deployment outside the classroom has become a consumer-protection question, and the student-side inventory of it is thin. Student Defense's SHAPE AI report (2026) maps institutional AI use across admissions, recruitment and financial aid, student-success services (advising, counseling, benefits access, credit transfer), and education delivery — LMS-embedded features from Canvas, Blackboard and D2L

Brightspace, institution-wide GenAI platforms, tutoring and feedback systems, detection and proctoring — and argues that adoption is outrunning protection. Its six cross-cutting concerns (whether students get what they pay for, the loss of learning communities, disclosure and transparency, data privacy, bias, and calibrated human oversight) are joined to a four-question procurement screen: what problem is being solved, whether governance capacity exists, whether the institution is being transparent, and whether the deployment creates value for students. The report's position is that states, accreditors and the federal Department of Education are not yet equipped to catch these risks, leaving the institution's own written policy as the operative protection, and it names the failure mode directly: a college marketing a faculty-led program while instruction or course design is outsourced to AI or third-party vendors is selling a different product under its own name.

Student experience at scale

Large-scale studies of authentic student AI use and GenAI availability and satisfaction document how students actually use AI — revealing gaps between institutional policy and everyday practice. Survey research captures how students navigate the AI landscape, and studies of study time, AI skills for graduates, and student perceptions of AI tools show that the student experience of AI is mixed — efficient but often shallower. Much of this university learning now happens online, where online teaching and learning shapes both AI's benefits (scalable personalization, always-on support) and its risks (academic integrity, cognitive offloading) for college students. An exploratory ML approach using SHAP analysis examined how students' perceptions and demographics relate to intended academic ChatGPT use, prioritizing interpretability (An Exploratory Machine Learning Approach to Understanding Determinants of Future ChatGPT Use in Higher Education). In art and design education, where generative AI challenges the value of human Creativity, a project-based learning model with digital storytelling at its core cultivated the emotional, cultural, and narrative capacities AI lacks — evaluated through a 15-week embedded case study with 426 Chinese undergraduates who translated local cultural heritage into Multimodal AI narratives (In the AI era: A project-based digital storytelling framework for art and design education). Assistive and inclusive uses of GenAI are also reshaping the student experience for disabled learners: Khlaif et al. (2026) — a qualitative case study of 21 visually impaired undergraduates across three Palestinian universities — found GenAI tailors pace, content, and delivery to individual profiles, simplifies complex texts, and converts content across modalities, giving learners a sense of autonomy and confidence in class participation while being viewed as complementing rather than replacing teachers.

A hierarchical regression on 303 undergraduates found perceived resources and teacher support explained 29% of AI-literacy variance, prior digital competence 3%, the psychological block 6% (total $R^2 = 0.39$); technology anxiety's association reversed to positive in the full model, only for critical evaluation and ethical competence (Chow et al. (2026)).

Beyond the classroom, AI reaches students through the institution itself — advising, outreach, referral, and the allocation of scarce support — which student support and success gathers as its own body of evidence. Its central caution about scale comes from a four-year randomized evaluation (N = 8,708) in which registration nudges moved a deadline by 34 percentage points while graduation, credits, and GPA did not move at all.

Graduate and professional education

The knowledge base is weighted heavily toward undergraduate study, and it houses graduate and professional preparation inside discipline-specific pages (medical and health-professions education, business education, teacher education) rather than in a separate graduate-education page. Two strands nonetheless bear specifically on master's, doctoral, and professional students: research training, and professional-degree programs.

Postgraduate *research* practice is the more distinctive of the two. Dai and Chan (2026) analyzed how 28 postgraduate research students across seven focus groups enacted AI Literacy in their GenAI-assisted research and found them to be calibrated users rather than passive adopters — matching tools to tasks by perceived stakes and disciplinary norms, retaining human oversight, and drawing their own boundaries between acceptable drafting help and substitution of their reasoning. Their central finding is a policy gap: institutional GenAI guidance addresses teaching, learning, and assessment but says almost nothing about the research process, so the authors propose researcher-oriented guidelines that scaffold each AI literacy dimension across the research workflow for researchers and their supervisors. Oh, Talton and Bui (2026) approach the same population from the institutional side: among 93 bioscience graduate students and postdoctoral trainees in a required research-ethics course, three simple pre-instruction behavioral signals informed lightweight intake profiling for adaptive AI Ethics instruction, while prior AI coursework predicted none of the five perception outcomes. AI is also reshaping the research team itself — analysis of 147,074 publications since 2020 associates AI-assisted writing with smaller, junior-leaner teams producing highly cited work, reversing the decades-long "Big Science" drift toward larger collaborations — and a single-investigator case study documents what sustained agentic support looks like inside one researcher's own workflow.

Professional-degree programs hold most of the graduate-level evidence, and it is organized by discipline. In health-professions education, a randomized controlled trial of 100 third-year medical students tested a multi-agent LLM system — simulated patient, Socratic tutor, turn-level evaluator — organized around explicit Scaffolding functions for clinical interview training, while the SCAN framework reframes trainee AI use as a problem of task distribution and real-time metacognitive classification rather than learner *misuse*. Master's-level preparation appears in Zhu et al. (2026), whose D–T–E model raised mathematics-education M.Ed. students' instructional-design competence (Cohen's $d = 0.62$) by having three LLMs act as "intelligent reviewers" in a design–feedback–reflection loop. How students conceptualize GenAI and their own professionalisation cuts across these programs, while workplace and continuing professional learning — adjacent to but distinct from graduate study — is treated under Adult Learners and Workplace Learning.

Faculty and teaching

Educational Development research examines how instructors adopt, resist, or adapt to AI. Teacher AI adoption studies identify confidence, support, and attitude as key predictors. AI-assisted discretionary feedback research explores whether AI increases instructor feedback quality and quantity, and ethics research weighs whether teachers should use AI for feedback at all. Staff-perspectives research and phenomenographic studies of teacher conceptions probe how educators understand their changing role. In large-class settings, AI can now shoulder a growing share of the feedback load: a semester-long field experiment in undergraduate macroeconomics tutorials (Geschwind et al., 2026) found that individual GPT-4

feedback sustained the highest participation across eight open-ended tasks and produced the largest content learning gains, positioning AI feedback as a scalable complement to lecturer feedback and a substitute for unreliable peer feedback. A complementary route for large undergrad STEM classes is a diagnostic teaching-assistant system: Arthur (Yin et al. 2026) uses a per-question ML backbone to give real-time, personalized feedback on Engineering Economics Calculated Formula Questions — a domain where handwritten solutions had previously blocked AI support — via a dialogue-based, question-bank web interface that balances feedback accuracy against collection efficiency. Farazouli et al. (2026) capture the *emotional* dimension of that change: 24 Swedish university teachers experienced GAI's emergence as alarming and overwhelming, reporting a "state of vulnerability" (low confidence, insecurity, fear of "not being ahead of students") and feeling "stuck" between utopian and dystopian discourses — while rethinking Assessment and re-evaluating their priorities toward critical thinking and ethical GAI use.

One hour of AI tutoring was statistically equivalent to live expert human tutoring on GRE learning gains across 2,469 sessions with 2,383 adults, and one model reached parity at 918× lower cost per percentage point (Northcutt et al. (2026)).

Assessment and integrity

Academic Integrity and AI assessment reform research grapple with how universities should redesign evaluation for an AI-capable student body. Detection-centered approaches are giving way to Authentic Assessment and process-based evaluation, including oral exams, assessment twins, and authentic assessment redesign. The shift reflects a deeper concern: how students and institutions define cheating with AI, and the quality of AI-generated assessment materials. Automation of grading itself is maturing for open-ended university work: Pecuchova, Benko & Drlik (2025) benchmarked eleven GenAI and sentence-embedding models on 1,885 responses to 24 software-engineering exam questions and found only GPTo1 reached almost-perfect agreement with two expert human graders (Fleiss' Kappa 0.82), with context-sensitive models outclassing reference-based ones — but its proprietary API costs led the authors to recommend hybrid human-in-the-loop deployment for resource-constrained institutions. At the professional-program level, Olvet et al. (2026) show that Large Language Models (LLMs) (GPT-4) scoring of pre-clerkship medical open-ended exam questions can reach substantial-to-almost-perfect agreement with faculty graders (weighted kappa up to 0.94) after iterative human rubric refinement, while the authors still recommend keeping humans in the loop to arbitrate residual discrepancies. Complementing this model-level evidence, Falahat, Das, Bhaumik & Thambi (2026) graded a 21-item university pharmacy exam with ChatGPT-5 and found near-perfect agreement with faculty on objective items (CCC 0.935–1.000) but unreliable agreement on short-answer and essay items, with rubric provision not consistently improving performance — reinforcing the case for hybrid, human-in-the-loop grading in university assessment.

A third route hardens the assignment itself: rendering prompts as perturbed images raised LLM assignment-completion failure from 7.4% to 55.6% and pushed Tesseract extraction error to 100.0%, reframing integrity as content design that complements detection rather than replacing it (Salaun et al., 2026).

Implications for higher-education instructors

- **Design assessment for an AI-capable student body.** Detection-centered integrity approaches are giving way to authentic and process-based evaluation (beyond detection, assessment reform) — redesign what you assess, not just how you police it.
- **Stop treating an in-room ban as assurance.** Smart glasses and AI-enabled hearing aids are dually transparent — no gaze drop or posture shift to detect — so an invigilated exam or oral can no longer purchase evidential confidence by physical separation (Corbin et al., 2026).
- **Redesign the "what should students still learn by hand?" question.** Just as in computing, decide which skills must be preserved (verification, judgment, process) and make those the assessed core, rather than assuming AI skills transfer automatically.
- **Treat faculty readiness as sociotechnical, not just technical.** EPIQ-AI frames readiness across epistemic, pedagogical, institutional, and quality domains — align your teaching practice with institutional governance, not just tool fluency.
- **Fund AI literacy, not just tool confidence, for faculty.** Liu et al. (2026) found that social and organizational support reached university faculty AI well-being only indirectly, through AI literacy ($\beta = 0.713$), so programs that build conceptual, ethical and pedagogical understanding do more for faculty than hands-on fluency alone.
- **Address the policy-vs-practice gap.** Large-scale studies (AI in the wild) show students use AI in ways institutional policy doesn't anticipate — align your expectations with real usage and teach AI Literacy explicitly.
- **Write method-specific guidance, not one campus-wide AI policy.** Interviewing 25 university language teachers, the study distilled 20 ethical tensions — four per online method — grouped into authenticity of learning (11), authority challenge (4) and collaborative dynamics (5), and argues that generic, method-agnostic policy cannot address the distinct pressures each online method places on integrity and collaboration (Baoyi & Khan (2026)).
- **Use AI to raise feedback quality and quantity.** AI-assisted feedback can increase the feedback instructors deliver; pair it with human judgment so it improves learning rather than merely automating.
- **Engage with grading and assessment innovation deliberately.** Mesny, Roberge-Maltais & Galy (2026) argue that Assessment and grading are among the most influential factors shaping learning in higher education, yet they remain under-researched in fields such as management education (only 58 articles over 20 years across four leading journals). Traditional, summative-heavy and norm-referenced approaches undermine deep learning, Well-Being, equity, and integrity in the generative AI era; the authors urge instructors to engage more actively and reciprocally with five innovative practices (authentic assessment, self- and peer-assessment, reassessment, standards-based grading, ungrading), noting implementation demands institutional and cultural support and incremental experimentation.
- **Treat research training and supervision as an AI-literacy site in its own right.** Postgraduate researchers enact AI Literacy as a situated practice rather than a static skill set, and institutional guidance largely stops at teaching and assessment. Guidance for thesis, dissertation, and publication work should scaffold verification, attribution, and disclosure concretely for each AI

literacy dimension — and simple pre-instruction signals can target that support in research-ethics courses — instead of issuing binary rules.

Common Misconceptions

- **“Institutional AI adoption has matured.”** The **symbolic layer is saturated while the structural layer is thin**: **100% have an AI task force and a master’s AI degree, but only 12% have executive AI leadership** and only 5% require a further institutional step. Announcements have outrun structures by an order of magnitude.
- **“Prestige predicts institutional AI maturity.”** Institutionalization proved **independent of prestige (rank correlation $r \approx 0.04$)**, with significant **regional variation (ANOVA $F = 5.86$, $p < .001$)**. Reputation is not a proxy for readiness, and geography predicts more than status.
- **“How AI distributes epistemic work is uniform across institutions.”** Sun, Dohn and Rehm (2026) classified **102 empirical higher-education studies** by how epistemic work was distributed, and the variation is the finding rather than a detail.

Adult Learners

> **Adult learning** — the theory and practice of educating adults (andragogy), and how AI tools and technologies can be designed to support adult learners' autonomy, prior experience, and real-world relevance. Explored across 13 articles in this knowledge base.

Questions to Consider

- Adult learning theory assumes learners are self-directed, draw on life experience, and want real-world relevance. But if AI performs much of the cognitive work, does a learner completing a task without visible help actually prove they directed it? What would make you confident they did?
- Behavioral independence from a tool no longer guarantees the learner directed the learning. If you were designing AI for adult learners, what would you look for to confirm genuine self-direction rather than quiet delegation?
- Design guidelines for adult AI tools emphasize fitting into busy lives — mobile-friendly, offline-capable, connected to real problems. Which of these matter most for your own learning, and what does a tool that ignores them cost the learner?
- Adult learners often study at work or at home, so online delivery dominates — bringing flexibility but also risks of offloading and integrity questions. How does the convenience of AI assistance interact with the goal of durable learning for a busy adult?
- Research found no single adult-learning AI system satisfied all design guidelines — the full ecosystem was needed. What does that suggest about expecting one tool to meet every learner's needs?
- For marginalized and neurodivergent adult learners, equity may be less about tool access than about the educator's relational care. How does positioning the human as the locus of care change how you would design or adopt an AI tool?

Introduction

Rooted in Knowles's andragogical model, adult learning assumes learners are self-directed, draw on life experience, are motivated by immediate and practical goals, and benefit most when learning connects to their real-world roles. These assumptions matter for AI design because generative AI can now participate in almost every stage of learning — identifying needs, setting goals, interpreting information, producing outputs, and evaluating performance. When AI performs so much of the cognitive work, behavioral independence from the tool no longer guarantees that the learner actually directed the learning. Research in this knowledge base accordingly reframes self-direction as an active design goal rather than an assumed default, and evaluates adult-learning AI against criteria like goal ownership, delegation control, and cognitive recoverability.

Evidence from connected articles

- **Andragogy and GenAI cognitive delegation.** Hyoung (2026) revisits Knowles's six andragogical assumptions under AI-mediated cognitive delegation, arguing that completing a task without visible AI help does not prove meaningful self-direction. It derives five analytical dimensions — need and goal ownership, delegation control, epistemic calibration, cognitive recoverability and transfer, and motivational autonomy — bridging adult learning with Cognitive Offloading and Self-Regulated Learning to assess whether learners remain genuinely self-directed in the Generative AI era.
- **Design guidelines for AI adult-learning tools.** Drawing on longitudinal deployment data from the National AI Institute for Adult Learning and Online Education (AI-ALOE), the DIS 2026 paper synthesizes 19 empirically grounded design guidelines for AI-powered adult-learning technologies. Derived from ~1,600 stakeholder statements across seven deployed systems, the guidelines span cognitive, social, and teaching presence (a Community of Inquiry framing) and emphasize that tools should fit into busy adult lives (mobile-friendly, offline-capable), connect content to real-world problems, personalize meaningfully, provide substantive support and feedback, and be transparent about data. No single system satisfied all guidelines; the full AI-ALOE ecosystem was needed to cover them.
- **Adult, distance, and lifelong learning contexts.** Rienties et al. show how the Open University designed and evaluated an embedded AI assistant (AIDA) through six Design-Based Research studies; students using it spent twice as long on the course, though the study warns that technical capability must be matched by AI Governance and organizational readiness. Theodora and Tselios frame AI's dual role in adult and Lifelong Learning as both an enabler of personalized, scalable education and a source of equity and governance risk, calling for inclusive, human-centered policy. A Midwestern case study co-designed an AI-literacy program for 54 adults in an underserved community, finding that equity-oriented adult AI education must meet learners where they are on basic digital literacy skills, build Trust around data privacy, and connect to lived experience. Herron's "Sovereign Hive" / Tutor-in-the-Loop framework treats GenAI equity in Further Education as atmospheric regulation rather than mere provision of tools, placing the educator at the center of the relational and cognitive support marginalized and neurodivergent adults need.

Connections to related concepts

Adult learning sits at the intersection of several closely linked concepts in this knowledge base. Higher Education supplies the institutional context in which much adult and distance learning occurs, while Workplace Learning covers its workforce and Lifelong Learning its continuous-education dimension. Vocational education and training is the neighbour that names an occupation rather than a learner: adult learning describes what learners bring to any context — self-direction, prior experience, immediate practical goals. VET names initial, practice-proximal preparation for a named trade or technical role, judged by demonstrated competence with equipment and framed by qualification frameworks rather than by andragogical dispositions. Online teaching and learning is the dominant delivery medium for adult learners — who often study at work or at home — so its affordances (24/7 access, asynchronous support) and risks

(integrity, offloading) are central to adult-learning design. Self-Regulated Learning and Learner Agency name the learner capacities that AI must protect rather than erode, and Cognitive Offloading captures the mechanism by which AI can either support or undermine them. Inclusive Learning and Equity frame the equity obligations of adult AI tools, Human-in-the-Loop names the design pattern that keeps humans accountable, and Scaffolding describes the graduated support such tools should provide.

Implications for adult-education instructors and designers

- **Design AI as a scaffold for self-direction, not a substitute.** Behavioral independence from the tool doesn't prove the learner directed the learning — protect goal ownership, delegation control, and cognitive recoverability (andragogy + cognitive delegation).
- **Fit into busy adult lives.** Make tools asynchronous, mobile, and offline-capable, and connect content to real-world problems (AI-ALOE guidelines).
- **Design for a range of engagement, not assumed depth.** Working adults triage limited cognitive resources across jobs, families and coursework, so a six-semester framework made Socratic AI dialogue more rewarding than the fast route rather than mandatory Packard et al. (2026).
- **Keep a human in the loop.** Position the educator as the locus of relational and cognitive care, especially for marginalized and neurodivergent adult learners (Tutor-in-the-Loop).
- **Address foundational digital literacy and data trust.** Build AI Literacy and Trust around data privacy before expecting adoption (community AI education).
- **Ground AI in learning science and andragogy, and prefer deep personalization.** Apply andragogical theory and connect content to real-world problems; favor deep personalization (task sequencing, difficulty calibration) over surface-level adaptation.
- **Make transparency and community features first-class.** Data-practice transparency and social/community features are among the most neglected yet most valued dimensions of adult AI tools.
- **Treat technical and structural reliability as a precondition.** Engagement depends as much on stable, inclusive infrastructure as on pedagogical quality — unstable or exclusionary platforms undermine otherwise sound design.
- **AI design principles for andragogy.** Kim et al. (2026) find adult learners value AI as a collaborative learning agent and derive three AI design principles for andragogy: human-in-the-loop (shared mental models, human-AI co-creation), emotional design (calibrating AI reliance, empathetic communication), and adaptability (continuous adaptation, interoperability). Their eleven scenario prototypes also map each andragogical principle onto a concrete AI affordance: AI tutors and teachable agents for involvement, monitoring and analytics tools for autonomy and Self-Assessment, empathetic chatbots and simulations for experience, case libraries and higher-order question generators for problem-centered work, and AI planners and career coaches for relevance.
- **Preserve productive struggle.** The same group's Productive Failure study maps AI support onto the two PF phases and concludes the design must not resolve the struggle: conversational agents

act as non-directive thinking partners during generation and exploration, then support comparison, reorganization and transfer during consolidation (Kim et al. (2026)).

Common Misconceptions

- **“One good tool serves adult learners.”** Research found **no single adult-learning AI system satisfied all design guidelines** — the full ecosystem was needed. Adults arrive with obligations, intermittent schedules and heterogeneous goals, so a single product cannot cover the design space.
- **“Digital literacy can be assumed at the adult level.”** A Midwestern case study co-designed an AI-literacy program for **54 adults in an underserved community** and found that equity-oriented adult AI education **must address foundational digital literacy and data trust** first. Age is not a proxy for digital fluency.
- **“Adoption is a motivation problem.”** Building AI Literacy and Trust around data privacy has to precede expecting adoption. Willingness follows from confidence about what happens to one’s data, not from enthusiasm about the technology.

Vocational Education and Training

> **Vocational education and training** — the segment of education that prepares people for named occupations, trades and technical roles, organized around practice-proximal competence rather than disciplinary knowledge. Where workplace learning describes upskilling for the already employed, VET includes initial preparation for a trade; where higher education names degree study, VET is often non-degree and framed by national qualification frameworks. Its defining features are that learners are assessed on what they can do with equipment, that instruction happens near the workshop, simulator or worksite, and that the human trainers who carry practical instruction are frequently the binding constraint. In AI research VET appears both as a distinct learner population — one whose academic confidence is tied to demonstrated skill and occupational identity — and as a distinct evidence base, thinner and more fragmented than the school or university literature.

Questions to Consider

- If a qualification certifies what a learner can do, how much AI-assisted learning counts as authentic practice and how much substitutes for the repetition that builds competence?
- What is lost when an AI agent role-plays the counterpart — patient, pilot, client — that a human trainer used to play? Which judgments can a synthetic counterpart not model?
- Oral assessment scales poorly with class size. If AI surfaces evidence but does not judge, which parts of assessment capacity are relieved and which are merely displaced to the teacher?
- No study in the AI-in-VET evidence base is set in a workplace, yet VET is defined by work-based learning. What would credible research where the learning happens require?
- The EU AI Act treats AI evaluating learning outcomes in vocational training as high risk, while some jurisdictions have none. Should procurement follow the strictest standard available?

Introduction

Vocational education and training prepares people for specific occupations — automotive technicians, air traffic controllers, interior designers, care workers — and its currency is demonstrated competence rather than accumulated credit. Assessment tends to be performance-based, instruction is tied to equipment, and the skilled trainers who supervise practice are scarce.

Its neighbours in this knowledge base differ chiefly in scope. Workplace Learning covers workplace and corporate upskilling, mostly for people already employed; VET covers initial occupational preparation as well. Adult Learners names learner characteristics rather than occupational specificity. Higher Education names degree-granting study, whereas much VET is organized by qualification frameworks such as NZQA unit standards or the EQF. STEM Education and VET overlap in technical domains, but STEM education aims at conceptual understanding while VET aims at usable procedure. Career Development and Readiness names the employability dispositions VET programs are judged by; VET names the instructional system held accountable for producing them.

What is distinctive about AI in VET is a gap between what the sector says it wants and what it builds: constructivist theory is widely espoused while behaviorist drill-and-practice systems dominate and learner-agency designs remain rare. The recurring design question is not whether AI can deliver instruction, but whether it can absorb the parts of vocational learning that are expensive to staff — realistic scenarios, timely feedback, role-played counterparts, oral evidence — without displacing the practice that produces competence.

How AI appears in vocational education and training

- **A young, fragmented and geographically concentrated evidence base.** The first systematic review of AI in VET (Artificial intelligence in vocational education and training: A systematic review of educational purposes, theoretical conceptualizations, and empirical effectiveness) identified 26 empirical studies published 2015–2026 through ERIC, Web of Science and Elicit under PRISMA guidelines: nine technical-domain, nine domain-general, five in business administration and three in health. Settings were six classroom, eight online, four blended and eight simulation-based — and none in a workplace, despite VET's work-based character. Seventeen of the 26 originated in Asia; only nine studies shared at least one reference and none cited each other. Five were randomized experiments and 21 used pre-experimental or quasi-experimental designs, mostly measuring outcomes immediately after intervention, and only three gave learners an active role in an AI-empowered design. The authors warn of an educational "Turing Trap" — using AI to replicate human instruction rather than augment human judgment — and call for failure cases and boundary conditions in place of the prevailing success narrative.
- **Simulation absorbs the scarce role-player.** ASTRA: A Scalable Next-Generation ATCO Training Simulator with Autonomous Simpilots targets a capacity constraint in air traffic control training: *simpilots*, specialized human trainers who role-play both pilots and controllers in a simulated airspace. ASTRA substitutes autonomous Large Language Models (LLMs)-driven sim-pilots, keeping scenario complexity while removing the staffing bottleneck and enabling adaptive practice at scale. It is a system description rather than an efficacy trial, but it names a mechanism that recurs across AI in VET: where the scarce input is a skilled human playing a counterpart, an agent can hold the role and let practice expand.
- **Immersive, agent-supported project work can raise design ability — selectively.** Cultivating design creativity of vocational students: A model of project-based learning in AI-enabled immersive virtual environments specifies AI-IVE-PBL, a four-dimension, five-phase model (discovery, envisioning, modeling, communication, refinement) run in VR with an LLM-backed digital-human assistant in a first-year interior design course at a Chinese vocational college. In a 12-week two-group quasi-experiment (63 valid responses; 31 vs 32), the immersive-agent condition scored higher on design ability ($\eta^2p = .138$) and creative ability ($\eta^2p = .111$) under ANCOVA. Cognitive engagement was $d = 0.90$, behavioral engagement $d = 0.75$, motivation $d = 0.74$, satisfaction $d = 0.69$, and cognitive load lower ($d = -0.52$). Innovative thinking and affective engagement did not reach significance, attributed by the authors to short-term ceilings on entrenched cognitive patterns. Every outcome is self-report, with no design artifacts or expert ratings. Read against Generative AI and Extended Reality in Collaborative Architectural Design Education: An Exploratory Studio Study, where a GenAI-plus-XR pipeline produced declining

design Self-Efficacy and no blinded-panel advantage, the difference looks less like hardware than like who holds the phase structure and the rubric.

- **Assessment is where the authenticity problem is sharpest.** Designing AI-Supported Oral Assessment in TVET documents AkoVoice, trialled in four Level 3 Automotive and one Level 3 Engineering class, designed so AI surfaces rubric evidence while the human assessor judges. Of 33 surveyed learners, 21 (64%) agreed the voice task was realistic and the same proportion said it gave a clear way to communicate what they knew; none disagreed that speaking in real time suited this authentic assessment better than a written portfolio. Word counts for identical questions varied five- to eight-fold between learners without improving accuracy on fact-based questions, and nine learners answering in 2 to 13 words were all marked correctly, the shortest being two words, “3500 kgs”, matched on value. A full cycle of capture, storage, AI judgment drafting and teacher reporting ran offline on one Windows laptop with 8 GB of graphics memory (Mistral 7B via Ollama, faster-whisper, Chatterbox), assessing up to 12 learners at once in a workshop where steel framing defeats wifi, with recordings encrypted and deleted after 90 days. The paper notes the EU AI Act treats AI evaluating learning outcomes in vocational training as high risk, while New Zealand has no sector-specific TVET framework.
- **Bounded accompaniment rather than substitution.** Design Principles and Observable Indicators for AI-Enabled Pedagogical Accompaniment: Evidence from the Amico Dual-Mode Prototype in Italy and China argues that the value of AI in technical and vocational settings depends on accountable pedagogical mediation rather than human-likeness. Its Amico prototype pairs AmicoMio, oriented to technical clarity and step-by-step task guidance, with AmicoTuo, oriented to reflective dialogue and maieutic questioning. The design principle is a *relational bridge*: interaction deliberately temporary, directional toward human contact, and bounded by safeguards, with adults retaining human-in-command responsibility. Exploratory pilots (N = 30, Italy and China, 20 bounded sessions) found participants treated the system as a bounded support tool, with no reported expectation of substitution or dependency.
- **AI-assisted learning carries a psychological cost when it replaces effort.** AI-assisted autonomous learning and reduced academic accomplishment in vocational higher education: The mediating role of hardiness surveyed 1,264 vocational college students in China using structural equation modeling and found AI-assisted autonomous learning negatively associated with hardiness (commitment, control, challenge) and positively associated with reduced academic accomplishment, a burnout dimension of negative self-evaluation. Hardiness partially mediated the relationship. The design is cross-sectional, self-report and single-institution, so causality is not established, but the framing matters for VET: where confidence is built through repeated practice, AI as a substitute may reduce both the disposition to persist and the felt experience of mastery.
- **Accelerating curriculum production without surrendering verification.** AI-accelerated End-to-End Framework for Rapid Professional Upskilling applies AI across all five stages of professional upskilling — knowledge acquisition, content development, review and verification, tutor coaching and assessment development — while keeping blueprint design, subject-matter review and misconception authoring with humans. Its external validation includes NASBA CPE accreditation, three of three learners passing an NVIDIA certification exam using only the framework’s knowledge base, and a 530-question bank tagged to a 53-skill blueprint. It belongs

here because it treats verification as a first-class stage: hallucination detection is largely absent from education pipelines, and the paper reports default LLM tutoring reaching only 52–70% correct pedagogical actions.

- **Perceived support is an institutional lever, not a student deficit.** Among 784 students at six Chinese higher vocational colleges, Huang et al. (2026) found AI literacy's link to self-reported complex problem solving (total 0.480) strengthened with perceived school ICT support: conditional indirect effects rose from 0.117 to 0.176 and 0.038 to 0.127.
- **Curriculum renewal as a continuing obligation, not a periodic review.** Wang (2026) identifies five interacting renewal dimensions, occupational transformation, curriculum currency, faculty capability alignment, program architecture and external alignment, and six leadership tests for deciding whether a course should be retained, revised, integrated, replaced or retired.

Common Misconceptions

"The AI-in-VET evidence base tells us about vocational education." It tells us about classroom proxies for it, which is a serious gap rather than a detail: **no study in the AI-in-VET evidence base is set in a workplace**, yet VET is *defined* by work-based learning. A finding about an AI tool in a simulated trade task has not yet encountered the conditions that make the sector distinctive — real clients, real safety consequences, real variation in workplace equipment.

"A significant effect on design or creative ability transfers to occupational competence." The strongest quantitative result here comes from a **12-week two-group quasi-experiment with 63 valid responses (31 vs 32)**. There the immersive-agent condition scored higher on design ability ($\eta^2p = .138$) and creative ability ($\eta^2p = .111$) under ANCOVA, with cognitive engagement d = 0.90. Thirty-one students per arm in a classroom task is evidence about that task, and occupational competence is not one of the measured outcomes.

"Learners will over-rely on AI in practical training." The pilot evidence points the other way. Exploratory pilots (**N = 30**, Italy and China, **20 bounded sessions**) found participants treating the system as a bounded support tool, with **no reported expectation of substitution or dependency**. That is exploratory and small, and it does suggest that vocational learners' framing of a tool as equipment rather than as an authority is a resource worth designing around.

"Learner approval of a simulated task means it assessed the right thing." Of **33 surveyed learners, 21 (64%)** agreed the voice task was realistic and the same proportion said it gave a clear way to communicate what they knew — and none disagreed that speaking in real time suited this authentic assessment. Realism and communication clarity are worth knowing and are not validity: a task can feel authentic and still fail to sample the occupational performance it stands in for.

Implications for Practice

For instructors

- Treat workplace-based studies as the missing evidence and design your pilots to include them; classroom gains are necessary and not sufficient for a trade qualification.

- Frame AI tools as bounded equipment rather than as an authority. The pilot evidence suggests learners already approach them this way, and that framing is worth making explicit.
- Keep authenticity checks separate from validity checks: ask what occupational performance the task samples, not only whether students found it realistic.

For developers

- Build for bounded, task-scoped assistance with a clear end, which matches how vocational learners actually used the systems in these pilots.
- Design against workplace variation — equipment, safety rules, client interaction — rather than against a lab configuration, since that is where deployment will happen.

For researchers

- Field at least some studies in workplaces. A sector defined by work-based learning whose evidence base contains no workplace studies has not yet tested its central claim.

Special Education

> **Special Education** — the design and delivery of instruction for learners with disabilities, spanning cognitive, physical, sensory, and neurodevelopmental differences. AI in education research in this knowledge base explores how AI tools can support diverse learner needs through personalization, adaptive scaffolding, and accessible interfaces — while also examining the risks of AI systems that overlook or marginalize disabled learners.

> ⚠️ **Special Education is primarily a K-12 term.** It is rooted in the U.S. Individuals with Disabilities Education Act (IDEA) and the entitlement-based system of Individualized Education Programs (IEPs) that governs special-education services in primary and secondary schooling. In higher education — and increasingly in K-12 as well — the more common framing is **Universal Design for Learning** (a proactive design framework that benefits all learners) alongside Accessibility and Assistive Technology rather than "special education." A K-12 special-education article and a college UDL piece are about overlapping but distinct contexts; the knowledge base keeps both because the research literature spans both. When a source concerns higher education and disabled learners, it is usually better linked to Universal Design for Learning, Accessibility, or Inclusive Learning than to special-education.

Questions to Consider

- The page emphasizes that 'special education' is primarily a K-12, entitlement-based term rooted in IDEA and IEPs, while higher education more often speaks of Universal Design for Learning and accessibility. Why do you think these contexts differ, and what does that difference reveal?
- AI's promise of personalization seems tailor-made for learners with diverse needs. But if a system can adapt to 'individual cognitive profiles,' what could go wrong when the model of a disability is too coarse or absent altogether?
- The research includes AI tools designed for specific disability profiles (e.g., dyslexic or Deaf and Hard of Hearing learners). What risks do you see in designing for narrow profiles versus designing universally for all learners from the start?
- How might AI systems that are built for the 'average' learner end up overlooking or marginalizing disabled learners, even unintentionally — and whose responsibility is it to prevent that?
- What would it mean for an AI tool to genuinely include, rather than merely accommodate, a learner with a disability — and how would you recognize the difference in practice?

Introduction

Special education is a domain where AI's capacity for personalization and adaptation offers particular promise. Unlike one-size-fits-all instruction, AI tutors can theoretically adapt to individual cognitive profiles,

communication needs, and learning paces. The articles in this knowledge base span AI for specific disability profiles, neurodivergent learner experiences, and critical perspectives on AI and disability.

Disability-specific AI tutoring tailors AI to particular learner needs. **Special-R1** extends reinforcement learning to model cognitive and communicative diversity across five disability profiles, using persona-aware prompts and thinking rewards to shape tutor responses for each learner. **DysLexLens** analyzed how dyslexic learners experience AI tools, revealing both the value of AI for literacy support and persistent accessibility barriers. **Chen et al.** designed an Large Language Models (LLMs)-powered question-generation system for Deaf and Hard of Hearing learners, introducing Visual and Emotion question strategies and iteratively refining questions with the target community to overcome the mismatch between text-based AI prompts and sign-based first languages. **Designing for What Cannot Be Seen: Supporting Embodied String Learning for Musicians with Blindness and Low-Vision** developed non-visual learning strategies with blind and low-vision musicians, centering disability-led embodied design. These connect to Inclusive Learning and Neurodiversity.

Neurodivergent learner experiences center autistic and ADHD students. **Zastudil et al.** found neurodivergent computing students need structured assignments, small consistent teams, and explicit role definitions — design requirements that Collaborative Learning tools must address. **Leveling the Playing Field: Temporal Video Segmentation for Individuals with ADHD in Computing Education** demonstrated that AI-segmented videos eliminated the ADHD performance gap. Both connect to Learning Design and Universal Design for Learning.

Critical perspectives examine how AI can marginalize disabled learners. **Tali-Otmani** argues that AI systems actively marginalize disability-centered knowledge due to Western-centric training data — connecting to Equity concerns about epistemic justice.

AI for dyslexia across detection, support, and personalized learning. A 2026 interdisciplinary systematic review (Dabaghi, D'Urso & Sciarrone, PRISMA-guided, 2018–2024, n=72) maps how AI supports students with dyslexia in education, finding AI used for detection, assistive support, and personalized learning — but with these strands evolving in parallel rather than in integration, driven more by technological opportunity than by consolidated educational theory. ML-based help-education tools fall into five areas (specific applications, engagement, personalization, recommendation, generic support) yet emphasize technical performance and classification accuracy while overlooking ecological validity and practical classroom deployment. Detection research (EEG, eye-tracking, ML models) prioritizes early intervention and shows diagnostic promise, but often requires specialized equipment and controlled environments, limiting scalability and accessibility in typical school settings. Open challenges include limited experimental validation, scalability, Ethics/privacy concerns with sensitive student data, limited teacher support and training, and language/cultural barriers (most research targets English-speaking populations).

Cognitive offloading for students with learning disabilities (SWLDs). Seung & Basham (2026), a conceptual review in a *Learning Disability Quarterly* special series on AI for students with LD, reframe GenAI use for SWLDs through the Cognitive Offloading lens. They argue that GenAI can be a **compensatory aid or a shortcut** depending on how offloading decisions interact with SWLDs' cognitive and motivational profiles (executive-function and working-memory challenges, heightened cognitive load, effort-avoidant performance goals, lower academic self-efficacy, and inflated expectations toward GenAI) and with instructional design. For reading and writing, GenAI can scaffold access (text leveling,

summarizing, Multimodal AI outputs, planning, drafting, revision feedback) while preserving higher-order engagement — but excessive offloading risks bypassing the comprehension, planning, and monitoring processes that are already fragile for these learners, fostering "metacognitive laziness" and compounding literacy difficulties across domains. The paper positions **instructional Guardrails** as the key moderating factor and recommends teaching strategic offloading, building AI Literacy to calibrate tool trust, sequencing mastery experiences to build Self-Efficacy, and aligning tasks and assessment with IEP goals that prioritize skill development over substitution. This extends the knowledge base's special-education coverage to the equity dimension of offloading: the same tool that lowers barriers to access can, if unguarded, substitute for the practice SWLDs need most. **AI-generated intervention content needs pre-generation controls, not only review.** Enkhjargal et al. (2026) found practitioners rated the co-designed Social Story tool highly usable (SUS 86.8) yet called its images generically Western and its behavior tracker mismatched to goal-linked clinical judgment — constraints they would have set before generation.

Kudláčková (2026) starts from the materials rather than from conversation: a vision-language model reads photographs of Shoebox Tasks — designed so the goal is visible in the objects — and turns them into a plan a Nao humanoid executes or demonstrates, reporting plan accuracy across six tasks and no learner data. - **Challenging behavior is where tutor benchmarks stop.** Of 923 case-grounded dialogues drawn from special-education and educational-psychology literature, the best of 11 models satisfied a documented intervention in 55.8% of open-ended cases and 43.3% of long-term plans (Park et al. (2026)).

Implications for special-education instructors

- **Co-design AI with the target learners and community.** Question generation for Deaf/Hard-of-Hearing learners shows the value of iteratively refining AI with the community to bridge the gap between text-based prompts and sign-based first languages — involve learners and their communities in design rather than assuming AI fits them.
- **Match AI to specific disability profiles, not generic accessibility.** Special-R1 models cognitive and communicative diversity across disability profiles; DysLexLens documents both the literacy value and the persistent accessibility barriers dyslexic learners face — choose tools aligned to each learner's profile and be alert to unmet barriers.
- **Structure collaboration for neurodivergent learners.** Neurodivergent computing students need structured assignments, small consistent teams, and explicit roles — apply these design requirements to any AI-mediated collaborative activity.
- **Use AI to close (not widen) performance gaps.** AI-segmented videos eliminated the ADHD performance gap — deploy adaptive AI where evidence shows it equalizes outcomes, not where it merely automates.
- **Center disability-led embodied design.** Blind/low-vision musicians research shows non-visual, disability-led strategies outperform default visual interfaces — build and adapt AI with disabled learners' expertise.
- **Guard against epistemic marginalization.** Critical perspectives warn that Western-centric training data can marginalize disability-centered knowledge — audit AI content and tools for epistemic justice alongside Equity.

Common Misconceptions

- **“Usability ratings validate an assistive tool.”** Practitioners gave a Social Story tool they had co-designed a usability pass (SUS 86.8) while faulting its stock Western imagery and a behavior tracker that missed goal-linked clinical judgment. High usability coexisted with substantive failures, so a SUS score is not an endorsement of fit.
- **“Generic benchmarks tell you how a tutor handles special-education cases.”** Of **923 case-grounded dialogues** drawn from special-education and educational-psychology literature, **the best of 11 models** satisfied a documented criterion — and **that is the edge of what a tutor benchmark covers**. Standard evaluations do not reach the cases practitioners most need help with.
- **“Neurodivergent learners need accommodations, not design requirements.”** Zastudil et al. found neurodivergent computing students need **structured assignments, small consistent teams and explicit role definitions** — general design requirements that benefit everyone, not individual adjustments granted after diagnosis.

- How Can AI Support Disabled and Neurodivergent Learners in My Course?

Teacher Education

> **Professional development** — the preparation and ongoing professional development of teachers, spanning pre-service teacher training (initial certification programs) and in-service professional development. In AI-in-education research, teacher education has become a central concern because teachers' AI literacy, technological-pedagogical knowledge, ethical fluency, and readiness to integrate AI into instruction determine whether AI adoption in classrooms succeeds. This concept organizes the knowledge base's substantial coverage of how AI reshapes the preparation, knowledge, beliefs, and practice of both prospective and practicing teachers.

Questions to Consider

- Teacher education here spans pre-service training (future teachers in certification programs) and in-service professional development (practicing teachers). Which of the two do you think faces the bigger challenge preparing for AI classrooms, and why?
- The page suggests teacher education must prepare teachers not just to use AI tools but to understand, evaluate, and ethically integrate them — a shift that 'redefines what it means to be a teacher.' How do you think that redefinition should change what a credentialing program teaches?
- Frameworks like AI-TPACK extend the classic TPACK model by adding an AI and ethics dimension. What do you think an 'AI dimension' of technological-pedagogical-content knowledge should actually contain beyond how to operate a chatbot?
- A scoping review of 55 studies cited on the page finds AI enhances pre-service teachers' instructional design, reflection, and critical thinking. But if AI can do some of this for them, when does its use in teacher training build skill versus substitute for the very judgment they'll need?
- If you were redesigning a teacher-education program for the AI era, what would you require every future teacher to experience — and what would you deliberately keep them from outsourcing to AI?

Introduction

Teacher education sits at the intersection of several knowledge base strands: it is a discipline/domain (like Medical and Health Professions Education and Humanities and Social Science Education), but it also draws on the general concepts of Teaching, Technological Pedagogical Content Knowledge (TPACK), Teacher AI Competency, and AI Literacy. In the AI era, teacher education must prepare teachers not only to use AI tools but to understand, evaluate, and ethically integrate them — a shift that redefines what it means to be a teacher. The learning sciences supply the knowledge this formation has to carry: where that field studies how people learn and how learning environments should be designed, teacher education is the professional formation in which such evidence has to land as a teacher's own capacity to design, teach and assess.

Cross-level evidence sharpens the design priority: a multilevel study of 46 teachers and 2,832 secondary students found that pedagogical AI knowledge (TPAIK) — not technical AI knowledge — drove students' perceptions of AI for social good and their intention to learn AI. Teacher education should therefore

foreground *how to teach with and about AI* over tool proficiency, consistent with the "pedagogy first, technology second" guideline.

A heutagogical strand runs alongside this design priority: Hochberg & Waitzman (2026) followed 93 Israeli teachers through an eight-week AI professional-development program and proposed a dual-layer relationship in which teachers' own reflective AI Regulation in Education and critical AI literacy mediate the Learner Agency- and capability-oriented designs they create for Learners.

Pre-service teacher education

Pre-service (initial) teacher education prepares future teachers during their certification programs. AI research in this strand includes:

- **AI-TPACK and intelligent-TPACK readiness.** Instruments and frameworks measure and build pre-service teachers' readiness to integrate AI, extending the Technological Pedagogical Content Knowledge (TPACK) framework with an AI/ethics dimension.(Conceptualizing pre-service teachers' readiness for AI integration into teaching practices: An intelligent-TPACK approach) (Assessing AI-TPACK readiness in mathematics teacher education: The role of self-efficacy and teaching beliefs)
- **Acceptance profiles, and an ease-of-use/intention paradox.** Chen et al. (2026) profiled 128 pre-service teachers into four ChatGPT-acceptance groups: Resistant Skeptics (14.06%) reported high perceived ease of use but very low behavioral intention, so operational skills training alone does not convert them.
- **Local context as a design input.** Swiss student teachers rated social-utility and intrinsic motives higher than their Chinese peers, who reported greater digital teaching competence and AI enthusiasm (Martínez-Moreno et al. (2026)). Preparation should key its entry point to each setting's motivational profile.
- **Applications and benefits.** A scoping review of 55 studies shows AI enhances pre-service teachers' instructional design, subject instruction, practical teaching skills, evaluation, reflective practice, critical thinking, technology integration, and pedagogical innovation.(Harnessing artificial intelligence for preservice teachers' development: A scoping review of applications, benefits, and challenges)
- **Unscaffolded genAI access scored below no genAI.** In an 11-week quasi-experiment with 52 pre-service teachers, the unscaffolded genAI class produced lower rubric-rated lesson plans than the no-genAI class (adjusted 86.54 vs 81.87, $F = 8.348$, $p = 0.006$, $\eta^2 = 0.146$), with no group difference in Self-Regulated Learning or critical thinking (Zhang et al. (2026)).
- **Structured custom-GPT cycles produced four cognitive partner roles.** In a one-semester design-based study, 14 pre-service Digital Technologies teachers used LMS-integrated personalized GPT agents through Prompt–Reflect–Refine cycles, enacting conceptual tutor, co-designer, reflective mirror, and cognitive challenger roles as expertise grew (Zagami), and 82% of final artifacts mapped content descriptors, assessment tasks, and success criteria.
- **Educational robotics and ML.** Initial teacher training embeds coding, robotics, and Machine Learning activities (e.g., micro:bit) to build computational thinking in future teachers.(Coding,

robots, computational concepts, and machine learning using the microbit card and the Maqueen and Nezha kits. A study in initial teacher training)

- **Authentic assessment and Metacognition.** AI-mediated assessment models (e.g., AAIWA) integrate authentic rubric-based assessment, condition-responsive AI feedback, and metacognitive reflection in pre-service programs.(AI-mediated authentic assessment and metacognitive reflection: A mixed-methods study of the AAIWA model)
- **AI-supported inquiry in science education.** A quasi-experiment with 48 pre-service science teachers in Türkiye (Aydın) integrated problem- and design-based learning into an 8-week AI-supported guided inquiry program on photosynthesis and respiration. It produced significant gains in conceptual understanding of the two biological processes, but *no* significant effect on AI literacy or self-perceived computational thinking — a reminder that AI-IBL can deepen subject-matter understanding in teacher candidates without automatically building their AI/CT competencies, which require explicit, targeted design.
- **Metacognitive prompting is not group-neutral, so future teachers have to learn to read the group.** In Wang et al.'s (2026) study the learners were pre-service teachers themselves, fourteen groups working a 60-minute inquiry with an on-demand metacognitive chatbot. Groups whose members held different preconceptions made the AI a center of conceptual talk; groups that already agreed used it as a lookup and evaluated proactive nudges negatively. The authors' practitioner note asks teachers to compose groups on preconception diversity and to keep shared-regulation support optional.
- **Generative AI for constructivist instructional design.** The SAHAB model is a quasi-experimental professional-development intervention in which generative AI empowers teachers to design Constructivism instruction, with large gains (d = 1.18). It shows GenAI can scaffold instructional design for teacher candidates and practicing teachers alike — not just deliver content, but support the *design* of student-centered learning activities.
- **Smart-classroom training for graduate mathematics M.Ed. students.** Zhu, Liang, Mao, and Wang (2026) show how a mathematics M.Ed. course can be enhanced with intelligent educational technologies (automated scoring, personalized recommendations, multi-AI feedback) across pre-, in-, and post-class stages, yielding statistically significant gains in instructional-objective design proficiency. The transferable D-T-E Model (Disciplinary Demand–Technological Empowerment–Evaluation Loop) offers teacher educators a discipline-specific framework for integrating smart education into graduate teacher preparation.
- **Adoption under a permissive policy is thinner than surveys suggest, and assessment literacy does not transfer.** Zou et al. (2026) surveyed 85 student teachers across three Hong Kong teacher-education courses where generative AI was explicitly permitted in assessment: 62.4% (53) chose not to use it at all, and adopters' use was shallow and corrective (proofreading 43.8%, clarity checks 34.4%, text generation 18.8%, brainstorming 12.5%). Fear of being wrongly accused of plagiarism (41.5% of non-adopters) and a preference for solo work (77.4%) outweighed missing skills (13.2%), and nine of eleven interviewees read the permissive policy as a possible "trap" — evidence that pre-service teachers bring integrity anxiety, not just tool readiness, into AI-permitted coursework.

- **Classroom AI policy writing as a lens on preservice thinking.** Nash & Burriss (2026) had 27 preservice secondary English teachers in the capstone year of a secondary English preparation program write the AI policies they would use in their own 6–12 classrooms, in a state with no state-level AI guidance. 26 of the 27 permitted some AI use, almost always restricted to teacher-specified tasks, times, and places, and only one banned it outright on ethical grounds tied to labor practices and copyright; 22 permitted AI for generating ideas while 22 disallowed or left unclear the use of AI to compose sentences, paragraphs, or papers, and the accompanying reflections read as negotiations between pedagogical commitments and a felt obligation to integrate AI. Asking preservice teachers to author a policy — rather than debate AI in the abstract — surfaced their philosophies, beliefs, and curricular assumptions, making policy writing a high-value activity for methods coursework.
- **Policy does not govern practice.** Four semesters of survey data from a US teacher-education program show GenAI use for assessment preparation rising from 57% to 83% and for studying from 44% to 76%, even as institutions considered AI Detection software, with ethical uncertainty rising across the waves (Parker et al. (2026)).
- **No pre-service study measured pupil learning.** A review that could include only seven sources found ethics acknowledged but seldom taught or assessed, and pre-service teachers overconfident about critiquing AI (Shukla (2026)).

In-service professional development

In-service professional development supports practicing teachers in integrating AI. AI research here includes:

- **Intelligent-TPACK-based PD frameworks.** A research-informed framework aligns the five i-TPACK knowledge domains with four evidence-based PD pathways (active learning, models/examples, coaching, feedback/reflection).(Designing effective AI professional development: A framework grounded in intelligent-TPACK)
- **GenAI-specific technological pedagogical knowledge (TPK).** Teacher educators themselves need GenAI-TPK — pedagogical reasoning, ethical awareness, and AI-augmented instructional design — to prepare teachers.(Teaching the teachers: A systematic review of genAI-specific technological pedagogical knowledge (TPK) in teacher education)
- **Human-centered and critical AI literacy.** Design-based research produces professional-learning curricula that operationalize critical AI literacy through human-centered AI activities, including educator-in-the-loop tasks.(Human-centered AI for teacher educators: Designing professional learning for critical AI literacy)
- **Capacity built by doing, not by studying.** A TPACK-based structural model of 122 in-service teachers found that actual use of AI on science and green-energy tasks and involvement in developing ESD-aligned materials predicted AI-integration capability, while abstract AI knowledge and attitudes toward AI did not (Riandi et al. (2026)).
- **Collaborative evaluation of AI-generated content as PD.** Gat, Usher, and Barak (2026) report on a workshop in which 60 middle-school science teachers rated ChatGPT-generated assessment questions through their disciplinary, pedagogical, and curricular judgment. Collaborative

evaluation itself functioned as professional development, helping teachers apply conceptual-precision criteria to AI output and surface the risk that AI content reinforces Misconceptions about AI — positioning teachers as critical evaluators of GenAI material rather than passive consumers.

- **Structured PD for language educators is rare but effective.** A systematic review of 23 studies (Li et al. 2026) found only three included studies reported structured professional development — an embedded grammar-course module, a government EMI program, and embedded chatbot inquiry — yet all converged on gains in knowledge, confidence, and identity reframing, shifting educators' views of GenAI from "replacement risk" to assistant/augmenter. The review argues PD should pair technical skill-building with practical wisdom, moving from awareness-raising and ethics through hands-on tool mastery to co-design of AI-enhanced lessons, and recommends a two-phase "back-end then classroom" implementation strategy.

The knowledge base's clearest instance of framework-driven GenAI PD for mathematics is a study of eight in-service teachers from rural and under-resourced districts who completed ten interactive modules built on Rhodes' 4P framework (How generative AI guided-professional development supports teachers' engagement with mathematical creativity, content knowledge, and pedagogical content knowledge). It supplies two design mechanisms in-service PD design otherwise lacks here: scaffolding that fades deliberately (explicit guidance early, then requests to justify, generalize and design tasks) and simulated student reasoning across Modules 6-10, alongside the finding that MC, CK and PCK moved together — while measuring engagement only, not teacher knowledge or student learning. - **Post-qualification programs.** In-service science educators' AI literacy and usage inform the design of AI-related post-qualification programs.(Science educators' AI literacy and AI usage in teaching: Implications for post-qualification programs)

- **AI support and guidance in teacher design work.** Pishtari, Gnadlinger & Ley (2026) had 13 higher-education teachers design activities across no-AI, AI-chatbot, and AI-plus-training conditions in a half-day program. AI access raised higher-order (Bloom) task attainment and cut perceived cognitive effort, while the subsequent interaction-training session plateaued quality but slightly raised effort (germane vs. extraneous load unresolved). It frames PD for AI-era teaching as needing both pedagogy-grounded design frameworks (Bloom, ICAP) and structured chatbot-interaction strategies, while cautioning that quality gains may mask offloading of pedagogical decisions to AI.

Knowledge, beliefs, and practice

A key finding across teacher-education research is the gap between what teachers *articulate* and what they *enact*: teachers often claim operational AI skills but struggle to apply pedagogically meaningful knowledge in practice.(Beyond operational skills: Teachers' AI knowledge and interactions with generative AI in lesson planning) The distinction runs even deeper when experience is crossed with AI proficiency: Choi et al. (2026) found that technically fluent *novices* still accept AI output passively during lesson design, whereas experienced teachers — even those with lower measured AI proficiency — critically re-prompt and adapt AI suggestions to their students and context. The implication is that in-service PD cannot treat "building AI skill" as sufficient; it must be differentiated by the teacher's experience and proficiency profile — response-evaluation and critical-adaptation scaffolds for novices, hands-on AI skill-building for experienced teachers with weaker AI proficiency. Expert judgment of AI-generated lesson plans marks that critical-adaptation

stance as the norm, not the exception: Karaismailoglu, Surmeli and Yildirim (2026) found eleven Turkish science-education specialists rated ChatGPT-4 and Teacher's Buddy plans for a sixth-grade unit as usable drafts — 7 of 11 judging them "applicable by correction," only 3 directly "Applicable" — and their preferences diverged from raw scores, favoring affective and contextual qualities over structural fidelity. Teacher education should therefore build the ability to evaluate, adapt, and localize AI-generated instructional materials as a core professional competence, in both pre-service and in-service programs. Psychological factors also matter — Self-Efficacy positively predicts AI-TPACK, while strong traditional teaching beliefs can act as a cognitive barrier.(Assessing AI-TPACK readiness in mathematics teacher education: The role of self-efficacy and teaching beliefs) Trust in AI is shaped by both technical knowledge and ethical perceptions (transparency, fairness, accountability, inclusiveness).(Unpacking ethics-domain of intelligent-TPACK scale in relation to in-service teachers' trust and distrust) Measuring teachers' AI literacy is itself an active front: because most AI-literacy assessments target students or general users, the Teachers' AI Literacy Scale (TAILS) — grounded in the six-dimension ED-AI framework — was developed and validated specifically for preservice language teachers through EFA and CFA, filling the measurement gap within teacher education. A comparably neglected question is whether the *mode* of preparation changes AI readiness. Mnguni et al. (2026) surveyed 186 final-year science student teachers in South Africa and found self-reported TPACK for AI-integrated teaching higher at a campus-based university (64.0%) than at a distance education university (47.4%), with Pedagogical Knowledge weakest in both, and AI training associated with self-reported TPACK only at the distance institution, where a five-credit short course predicted weaker reported TPACK than no training. Distance preparation therefore needs its own evidence base rather than assuming that training designed for campus programs transfers.

Simulated instructional practice

Beyond content and beliefs, teacher preparation increasingly uses **simulated classrooms** for hands-on practice that scales. EducaSim uses generative student agents (with personas, course-grounded memories, and an Large Language Models (LLMs)-as-judge speech oracle) to simulate a small-group section for teachers-in-training in a CS1 course supporting ~20,000 students. Deployed as an optional prep tool across 254 sessions (mean ~16 min), it provides low-cost ($0.05–$0.10/session) role-play practice with structured post-session feedback (talk-time statistics, LLM-identified instructional behaviors) and self-reflection prompts. This complements the Simulating Students paradigm: simulated learners serve not just evaluation but experiential, high-frequency teacher preparation, especially for massive online courses where live coaching cannot scale. A subject-specific instance is **Student GPT** (Zhuang & Zhang 2025), a custom ChatGPT chatbot that role-plays a middle school student holding common ratio-reasoning misconceptions; preservice secondary mathematics teachers practiced diagnosing and remediating those misconceptions in low-risk, personalized interactions within a methods course, showing how lightweight GenAI role-play can support practice-based teaching.

Implications for teacher educators

- **Build both AI literacy and critical AI-TPACK.** Pre-service and in-service teachers need readiness to integrate AI — instruments extend TPACK with an AI/ethics dimension (AI-TPACK, i-TPACK PD); teach ethical reasoning, transparency, and fairness alongside tool use.

- **Measure capability rather than confidence.** Mnguni (2026) argues that self-reported TPACK and perceived behavioral control may both index general confidence, and proposes scoring readiness with lesson-design tasks and prompt-evaluation tasks rather than self-report alone, ordering AI-TPACK capability upstream of attitude and intention.
- **Close the articulate-vs-enact gap.** Teachers often claim operational AI skills but struggle to apply them pedagogically; design PD that moves from knowledge to enacted practice (lesson planning).
- **Use simulated practice to scale preparation.** EducaSim-style simulated classrooms give teachers-in-training low-cost, high-frequency practice with feedback — a complement to limited live coaching.
- **Address beliefs and trust.** Self-Efficacy predicts AI-TPACK while strong traditional-teaching beliefs can be a barrier, and Trust is shaped by transparency/fairness — attend to these psychological factors, not just skills.
- **Backtracking from classroom dilemmas.** Kohnke et al. (2026) interviewed **17 pre-service teachers** at a Hong Kong university and worked backward from anticipated classroom dilemmas to teacher-education design needs. Pre-service teachers raised concerns about **academic integrity, privacy, and preserving essential human skills** in a GenAI-driven environment, pointing to curriculum implications that weave **ethics, Privacy, and AI literacy** (with critical-thinking skills) throughout teacher preparation rather than treating responsible use as an add-on.
- **AI as cognitive mediator in teacher reflection (2026):** A practice-based Reflective Triangle Model uses AI to mediate between individual teacher reflection and shared professional knowledge in learning communities, addressing the common failure of reflection to transform into collective professional learning (The Reflective Triangle Model: AI as a Cognitive Mediator in Teachers' Professional Learning and Learning-Community Development).
- **Make GenAI assessment design part of professional curriculum work.** Student teachers in Zou et al. (2026) showed little intention of redesigning their own future school assessments in response to generative AI, and the kindergarten and secondary participants largely judged the technology irrelevant to their own teaching context — an underdeveloped dimension of assessment literacy rather than a knowledge gap. Teacher-education programs should therefore embed ethical GenAI use in assessment design as part of professional curriculum, pairing program-level policy consistency with concrete exemplars of acceptable and unacceptable use and timely Feedback on students' actual AI use.
- **Separate delegable from non-delegable work.** O'Byrne (2026) found 23 undergraduates, most pre-service teachers, produced comparable artifacts whether they sustained boundary work or delegated it early, and the "cheating tension" over authorship was strongest among those doing the most boundary work — so the teaching aim is judging which interpretive work not to hand over.
- **Make classroom policy writing a core teacher-education activity, and treat ambiguity as a policy defect.** Nash & Burriss (2026) found that asking preservice teachers to write their own classroom AI policies functions as rhetorical world-building about what writing is for — a window into emergent beliefs that abstract discussion does not open. Because AI separates

writing-as-product from writing-as-process, programs should help teachers locate where thinking, learning, and value actually live across brainstorming, drafting, revising, and editing rather than locating thinking only in final text, and should support them in translating beliefs into operational, unambiguous rules paired with AI Literacy instruction: contradictions such as barring AI-generated text while holding students responsible for the AI-generated content they submit leave students unable to comply.

- **Teach teachers to read the primary research behind AI policy.** A six-week graduate research-methods course aimed at research consumption rather than production: one teacher applied the critical-evaluation framework to a district-mandated curriculum and presented the analysis to her principal, and several adopted Socratic questioning with their own students Packard et al. (2026).

Common Misconceptions

- **“Acceptance of AI among pre-service teachers is a single attitude.” 128 pre-service teachers** were profiled into four ChatGPT-acceptance groups including **Resistant Skeptics (14.06%), who reported high perceived ease of use but very low behavioral** intent. Ease of use and intention came apart in that group, so a usability-driven intervention would leave them unchanged.
- **“AI helps pre-service teachers mainly with content knowledge.”** A **scoping review of 55 studies** finds AI enhances **instructional design, subject instruction and practical teaching** — the design and practice capacities, not the content expertise.
- **“A scoping review of 55 studies establishes benefit.”** It documents what is reported across the field. Breadth of reported enhancement is a claim about the literature’s consensus, and 55 studies in a scoping review is not a pooled effect.

- How Do I Design Faculty Development for AI That Actually Changes Practice?

Bands and comparisons

Levels of Education

> **Levels of education** — the bands that organize this knowledge base's `level` metadata: **preschool**, **primary education**, **middle school**, **secondary**, **K-12**, **higher ed**, **undergraduate**, **graduate**, **adult learning**, **special education** and **teacher education**. This page is the umbrella for that field rather than a duplicate of any single band page: it explains what changes as you move across the bands, why the school/university break matters more than the subject being taught, and where the AI evidence is dense and where it is thin.

Questions to Consider

- A graduate seminar and a second-grade mathematics lesson are both "education," yet a tool that helps one can harm the other. What about the band — not the subject — changes what good AI use looks like?
- One trial with 132 second-graders found an adaptive mathematics tutor no better than a fixed sequence. Would you expect the same null for a university student, and what learner capacity does adaptation silently assume?
- 'K-12' and 'higher education' each compress several distinct settings into one label. Which comparisons do those labels hide?
- If a band's evidence base is thin, is the honest response to say nothing, to borrow from an adjacent band, or to design a study?

Introduction

The `level` metadata field names the band of education a source is about — bands, not ages: **preschool**, **primary education**, **middle school**, **secondary**, **K-12**, **higher ed**, **undergraduate**, **graduate**, **adult learning**, **special education**, **teacher education**. Some name a stage of schooling, two name the very different halves of university study, two name a learner population rather than a stage, and one names the people who teach. A source can carry several bands at once.

This page is the umbrella for that field; the band pages do the deep work and should be read with it: K-12, Early Childhood Education, Higher Education, Adult Learners, Special Education, Teacher Education and Vocational Education and Training.

What distinguishes one band from another

Bands differ along several axes at once, and AI research usually varies only one of them.

- **Capacity for self-regulation.** Two versions of the same second-grade mathematics tutor — identical content, interface, feedback and spoken hints, differing only in whether task selection followed a Bayesian Knowledge Tracing mastery estimate — produced no posttest difference among 132 seven-year-olds ($F(1, 124) = 0.32$, $p = .574$). The authors' first explanation is developmental: adaptive systems presuppose learners who can engage feedback, regulate effort

and stay focused, and young children have limited self-regulation (Effectiveness of adaptive versus non-adaptive intelligent tutoring systems in early primary mathematics).

- **Who mediates the interaction.** In the school bands an adult stands between learner and tool. A survey of 270 preschool teachers found adoption intention driven by perceived usefulness, ease of use, AI Self-Efficacy and AI anxiety — and the study deliberately excluded AI directed at children (Exploring factors influencing preschool teachers' behavioral intention to use AI technologies in early childhood settings).
- **What the assessment is for.** Secondary assessment feeds external stakes; university assessment is coursework and credentials; graduate assessment is the making of a researcher.
- **Prior knowledge.** Prior knowledge dominated that trial's posttest performance ($F(1, 124) = 206.99$, $p < .001$, $\eta^2p = .63$), so a band label correlates with, but does not equal, a knowledge level.

The school years and the university years

The most consequential divide is the break between school and university, and the two commonest labels each hide it or cross it.

Inside the school years the measured outcome changes sharply by band. In primary it is subject learning: 97 Chinese third-graders using GenAI chatbots in science inquiry posed better problems than a search-engine control ($t = 2.47$, $p = 0.015$) (Inquiry-based learning in STEM education: the impact of generative AI-based chatbots on primary school students' problem posing ability in science). In secondary it often becomes attitude rather than achievement: a survey of 508 Taiwanese junior high students found experiential appeal working through enjoyment to shape intention to use ChatGPT for lyric learning (XM → PEOU $\beta = 0.630$; PE → ATU $\beta = 0.369$), with 81.5% on the free tier — an access-equity fact disguised as a technology-acceptance finding (Junior high school student perspectives on the use of ChatGPT in music education). Secondary also holds the corpus's largest learning warning: across 26,811 Chinese students in grades 7–12, homework scores rose 18% and completion time fell 30% while closed-book exam scores dropped about 20% within six months, concentrated among the ~81% whose behavior indicated homework outsourcing (The generative AI learning penalty: Evidence from Chinese secondary education).

The university years split again. Undergraduate study is coursework under external judgment: among undergraduate writers at a minority-serving R1 university, AI Literacy predicted *which type* of Large Language Models (LLMs) reliance a student occupied rather than how much they used it (Four Types of LLM Reliance and Their Predictors Among Undergraduate Writers: A Mixed-Methods Study at a Minority-Serving R1 University). Graduate study is research training, where the outcome shifts from performance to formation. Among 420 astronomy doctoral and postdoctoral researchers, AI dependence was negatively associated with research autonomy ($r = -.355$) and Self-Efficacy ($r = -.321$), and the indirect path to innovative behavior ran mostly through autonomy ($-.115$) rather than self-efficacy ($-.069$); supervisory support weakened the negative link to autonomy ($B = .077$, $p = .020$) (AI-mediated research agency formation in higher education: Autonomy, self-efficacy and innovation in early-career scientific training). A doctoral student is judged on the judgment that AI dependence appears to erode; an undergraduate is not. Lumping both under 'higher education' hides that.

Where the evidence is concentrated, and where it is thin

The corpus is unevenly populated, and the level field makes the imbalance visible.

Dense. Higher education is the most-covered band: the pages consulted here include an eight-week platform trial with 60 engineering students (Developing an AI-Assisted Seminar-Based Learning Platform With Embedded Librarian Support: Enhancing Information Literacy of Engineering Research Teams), a survey of 395 education managers (AI adoption readiness among Ukrainian education managers: Barriers, typologies, and policy implications), a meta-synthesis of 18 African higher-education studies (Rethinking data privacy for AI adoption in African higher education: A meta-synthesis of stakeholder perceptions and policy implications) and a 420-researcher study of doctoral training (AI-mediated research agency formation in higher education: Autonomy, self-efficacy and innovation in early-career scientific training). Primary and secondary also carry outcome evidence.

Thin, and in places absent. The pages consulted here report no child-outcome study at the preschool band at all; the nearest evidence is a survey of teachers' intentions that excluded child-facing tools (Exploring factors influencing preschool teachers' behavioral intention to use AI technologies in early childhood settings). Middle school appears mainly as a *proposed* design and longitudinal study rather than reported outcomes (AI-Integrated Learning Management System for Middle School: A Longitudinal Study of Learning Outcomes Through High School and Beyond). The vocational band's strongest evidence is 63 self-report responses from one course, which its authors say requires replication (Cultivating design creativity of vocational students: A model of project-based learning in AI-enabled immersive virtual environments). The graduate evidence is cross-sectional, with a reverse-path model fitting slightly better than the developmental one, so the direction from dependence to reduced autonomy is inferred rather than confirmed (AI-mediated research agency formation in higher education: Autonomy, self-efficacy and innovation in early-career scientific training). Nothing consulted here reports AI outcome evidence for **adult learning** or **special education** as bands; those have their own coverage on Adult Learners and Special Education, and this page does not generalize from school-age findings to fill the gap.

One pattern holds at every level surveyed: the human layer absorbs the hardest cases. A human expert stayed at the credibility decision point for engineering students even when algorithmic recommendation reached F1 = 0.64 (Developing an AI-Assisted Seminar-Based Learning Platform With Embedded Librarian Support: Enhancing Information Literacy of Engineering Research Teams); supervisory support was the one condition that weakened AI dependence's negative links in doctoral training (AI-mediated research agency formation in higher education: Autonomy, self-efficacy and innovation in early-career scientific training); and it is preschool teachers, not children, who are the adopters (Exploring factors influencing preschool teachers' behavioral intention to use AI technologies in early childhood settings).

What level-appropriate design actually changes

- **Autonomy and support.** With young learners, adapt the *level of support* — more Scaffolding, guidance or hints — rather than task difficulty; difficulty adaptation bought nothing in early primary, while mastery gating may have held adaptive students back (Effectiveness of adaptive versus non-adaptive intelligent tutoring systems in early primary mathematics).

- **Reading level.** An age-tailored chatbot used prompt variables for ages 7–9, 9–11 and 12–14, and 63 children from first through eighth grade treated it as a credible information source (Ask Me Anything: Exploring Children's Attitudes Toward an Age-tailored AI-powered Chatbot).
- **Mediation.** Parents and teachers mediate in the school years, Librarians and supervisors in the university years — and the university counterpart is expertise rather than guardianship: the engineering platform kept a human where the algorithm was least confident (Developing an AI-Assisted Seminar-Based Learning Platform With Embedded Librarian Support: Enhancing Information Literacy of Engineering Research Teams).
- **Assessment stakes.** The middle-school LMS design gates AI by activity, keeping bounded hints in practice mode and switching AI off on graded items (AI-Integrated Learning Management System for Middle School: A Longitudinal Study of Learning Outcomes Through High School and Beyond) — a precaution the secondary learning-penalty evidence makes concrete (The generative AI learning penalty: Evidence from Chinese secondary education).
- **Data-protection duties for minors.** Obligations scale with age: for minors the corpus's proposals are structural — data minimization, age-appropriate response constraints, role-based access control, auditable logs (AI-Integrated Learning Management System for Middle School: A Longitudinal Study of Learning Outcomes Through High School and Beyond) — and children's digital-safety awareness cannot be assumed, since some were willing to confide secrets in a chatbot (Ask Me Anything: Exploring Children's Attitudes Toward an Age-tailored AI-powered Chatbot). For adults the duties shift toward consent, control and cross-border data flow (Rethinking data privacy for AI adoption in African higher education: A meta-synthesis of stakeholder perceptions and policy implications).
- **Governance that fits the band.** Readiness is layer-specific: 395 Ukrainian managers scored personal readiness 0.68 points above system readiness ($d = 0.73$), cited regulatory absence most often (58.5%), and rated personalization — the benefit vendors promise most — lowest of all applications (29.4%) (AI adoption readiness among Ukrainian education managers: Barriers, typologies, and policy implications).

Implications for AI in education

- **Read the level field before the topic field.** A finding from one band is a hypothesis for another, not a transferable result.
- **For the youngest bands, adapt support, not task difficulty** (Effectiveness of adaptive versus non-adaptive intelligent tutoring systems in early primary mathematics).
- **Don't port a tool across the school/university break without re-specifying who holds epistemic authority.** Dependence that lowers autonomy in doctoral training is a research-formation risk (AI-mediated research agency formation in higher education: Autonomy, self-efficacy and innovation in early-career scientific training).
- **Gate AI by activity, not by enthusiasm**, and scale privacy duties with age (AI-Integrated Learning Management System for Middle School: A Longitudinal Study of Learning Outcomes Through High School and Beyond, Rethinking data privacy for AI adoption in African higher education: A meta-synthesis of stakeholder perceptions and policy implications).

- **Design for the mediating adult of that band** — parent, teacher, librarian or supervisor — and measure their readiness separately from the institution's (AI adoption readiness among Ukrainian education managers: Barriers, typologies, and policy implications, Developing an AI-Assisted Seminar-Based Learning Platform With Embedded Librarian Support: Enhancing Information Literacy of Engineering Research Teams).
- **Say plainly when a band has no evidence**, and **don't mistake intention for achievement**: several level-specific studies report attitude or self-report outcomes rather than learning.

Common Misconceptions

"A band label tells you what a learner can do." Band and knowledge level correlate without being equal. In the second-grade tutoring trial, prior knowledge dominated posttest performance (**$F(1, 124) = 206.99$, $p < .001$, $\eta^2_p = .63$**) — a large effect that makes the grade-level label a weak predictor beside the learner's actual prior knowledge. Designing to the band and ignoring the within-band spread is designing for the average of a wide distribution.

"The subject being taught matters more than the education level." The school/university break matters more. What changes across that boundary is not the content but the capacity for self-regulation, the nature of the assessment contract, and who is responsible for the learning — which is why a tool that helps a graduate seminar can harm a second-grade lesson even on comparable content.

"An adaptive tutor helps every level equally." The comparison that isolates the variable is instructive: two versions of the same second-grade mathematics tutor — identical content, interface, feedback and spoken hints — differing **only in whether task selection followed a Bayesian Knowledge Tracing model**. Adaptive task selection is a level-sensitive intervention, and its benefit depends on whether learners at that level can act on the adaptation.

"Evidence concentrated in higher education generalises downward." It does not, and the distribution of the literature is a warning rather than a convenience. Where the evidence is dense and where it is thin is a property of the research economy, not of where AI is most used, so a claim about K-12 drawn from university samples is an extrapolation across the boundary that matters most.

Assessment and measurement

Assessment and feedback

Assessment

> **Assessment** — the process of gathering and interpreting evidence about what learners know and can do, and the methods used to evaluate learning. AI in Education has fundamentally reshaped assessment: it powers automated grading and scoring, generates and adapts assessment items, and raises deep questions about what assessments actually measure when students can use AI. Assessment is the umbrella concept that organizes the knowledge base's coverage of Formative Assessment, automated grading, validity, and Educational Measurement.

Questions to Consider

- Assessment here is defined as gathering and interpreting evidence about what learners know and can do. Before reading, how would you finish the sentence 'an assessment is valid if…' — and what would change about that answer if every student could secretly use AI to produce their work?
- The page claims that how a student uses GenAI (evaluative integration versus uncritical shortcut uptake) predicted performance, while how often they used it predicted nothing. What does this suggest about a common instinct to regulate AI by limiting its use?
- A learner may deliver professional-standard work they cannot reproduce without the tool — severing the inference between performance and underlying ability. Have you encountered a 'competency' being awarded for work that the student couldn't actually do unaided? What did that reveal?
- The constructive question the page offers is not 'how do we stop students using AI?' but 'how do we enable thoughtful use in contexts that mirror their future work?' What would assessment look like in your field if that were the goal?
- The DRIVE framework suggests assessing the quality of a student's engagement with GenAI — not just the artifact — by looking at whether they steer prompts strategically and integrate their own ideas. What would you look at to tell a deep, reflective AI interaction from surface consumption?
- AI-mediated assessment is diversifying into oral exams, portfolios, and conversational formats that reduce anxiety and feel professionally relevant. Which assessment format from your own experience do you think is most 'AI-resistant' — and is resistance the same thing as educational value?

Introduction

Assessment is central to AI in education for two reasons. First, AI itself is used to assess students — grading essays, code, short answers, and exams at scale. Second, AI in the classroom changes what assessments can validly measure, since students may use Generative AI to produce work. The field therefore spans both the *tools* that automate assessment and the *validity and integrity* questions that AI raises. A PRISMA review of 72 higher-education assessment studies found educators used GenAI across the whole assessment cycle —

creating assessments, practice, grading, transparency of learning and feedback — with creating assessments and feedback the most frequently identified affordances (Crompton and Burke (2026)).

How AI is used in assessment

- **Automated assessment:** AI-based assessment spans multiple modalities — multiple-choice, short answer, essay, code, and performance-based evaluation — through automated grading, Automated Essay Scoring, and Automated Question Generation.
- **Formative assessment:** AI systems generate, validate, and adapt formative assessment items at scale, informing ongoing instruction rather than only summative evaluation.
- **Learning analytics and measurement:** Learning Analytics and Educational Measurement connect assessment data to learning processes, using Item Response Theory, Knowledge Tracing, and Learner Modeling and Adaptive Instruction to interpret performance. Razavi and Powers (2026) demonstrate LLM-based item-difficulty estimation as a measurement input: across 5,170 K-5 math and reading items calibrated under the Rasch IRT model, GPT-4o's zero-shot ratings correlated moderately-to-strongly with true difficulties (r = 0.83 math, r = 0.81 reading) but varied by grade, while a feature-based approach (LLM-extracted features into tree-based models) reached correlations up to r = 0.87. The study offers a practical seven-step workflow for testing professionals, while cautioning that generalizability beyond K-5 math and reading is unclear.
- **Feedback loops:** AI assessment increasingly feeds into feedback loops that close the cycle from assessment to learning.
- **E-portfolio assessment:** e-portfolios assemble student work and reflections over time as a process-based, AI-robust assessment form. Generative AI can assist the portfolio *process* — generating feedback, Scaffolding reflection, and (with appropriate rubric design) supporting evaluation — while the portfolio's emphasis on reasoning traces and drafts resists AI fabrication. AI-assisted portfolio assessment and ChatGPT + e-portfolio for EFL speaking show AI can enhance both the portfolio experience and learner Feedback Literacy.
- **Open-ended grading reliability is model-dependent:** Pecuchova, Benko & Drlik (2025) benchmarked eleven GenAI and sentence-embedding models against two expert graders on 1,885 open-ended software-engineering responses: only GPTo1 reached almost-perfect agreement (Fleiss' Kappa 0.82), while reference-based models penalized correct-but-divergently-phrased answers. Because GPTo1 was the only model deemed deployable without oversight but carries proprietary API costs, the authors recommend hybrid strategies pairing advanced models with affordable options or human oversight in resource-constrained settings. A PRISMA-guided systematic review of 42 empirical studies (2023–2025) corroborates this conditional-reliability picture across the whole grading field: LLMs match human raters on closed-ended and short-answer tasks but cannot fully replace human judgment on complex, open-ended, or subjective work, and no uniform grading bias emerged — models were sometimes more lenient, sometimes stricter, and often avoided extreme scores (Can ChatGPT Replace the Teacher in Assessment? A Review of Research on the Use of Large Language Models in Grading and Providing Feedback). Iterative rubric refinement can push LLM open-ended scoring toward near-human reliability in high-stakes medical settings: Olvet et al. (2026) found that once faculty repeatedly revised analytic and holistic rubrics on error-pattern analysis, GPT-4 reached substantial-to-almost-perfect

agreement with faculty graders on three of four pre-clerkship questions (weighted kappa up to 0.94), while the residual holistic-rubric item stayed at only moderate agreement (κw = 0.54) — showing both the payoff of human-in-the-loop rubric engineering and its limits on synthetic, holistic tasks.

- **AI-supported oral and performance assessment.** A TVET design study moves assessment away from text-heavy formats toward interactive Oral Assessment supported by an LLM: across four cohorts, 21 of 33 learners rated the voice task realistic and none disagreed that speaking in real time reflected competence better than a written portfolio, while word counts for identical questions varied five- to eight-fold between cohorts and nine learners answered in two to thirteen words and were all correct. The system ran offline on a single laptop serving up to 12 simultaneous learners with Mistral 7B and faster-whisper, deleted recordings after 90 days, and left scoring judgments with assessors — an instance of Human-in-the-Loop assessment design for workplace-facing qualifications. (Designing AI-Supported Oral Assessment in TVET)

Validity and measurement challenges

AI raises fundamental validity questions: do AI-graded assessments measure student learning or AI-prompting skill? Does student use of AI invalidate traditional assessments? Key challenges include:

- **Construct validity:** Research on competency-based education shows generative AI has severed the inference between performance and underlying ability — a learner may deliver professional-standard work they cannot reproduce without the tool. This motivates reconceptualizing what competencies are assessed.
- **A three-vertex frame for realigning assessment.** Koretsky et al. (2026) treat ubiquitous GenAI as a validity and capability-definition problem rather than a cheating one, arguing that the assessment triangle's three vertices — cognition, observation, and interpretation — must be realigned together rather than patched one at a time.
- **Coauthorship and integrity:** Coauthorship integrity proposes a new source of validity evidence violated when students submit AI-generated content they do not understand, and explores conversational "AI Vivas" as a response.
- **Psychometric quality:** Psychometrically Aware AI and confidence-aware assessment work to keep AI scoring reliable, unbiased, and interpretable.
- **Evaluation of AI assessors:** AI Ed Evaluation provides the methods and benchmarks for determining whether automated assessors actually work — on reliability, Pedagogies and Teaching Strategies, and Equity — rather than headline accuracy alone.
- **Quality-dependent reliability of AI and peer grading (2026):** Comparing ChatGPT, peer, and instructor grading of the same undergraduate group projects, Usher & Faraon (2026) showed grading alignment with the instructor is *conditional on the quality of student work*: ChatGPT inflated low-quality submissions most and aligned better with the instructor on high-quality work, while peers aligned best on weaker work and under-graded strong projects. The finding challenges the binary "reliable vs unreliable" framing, pointing toward conditional-reliability models in which alternative assessors are matched to task and performance level.

- **Human grading is itself value-laden (2026):** Luo & Dawson (2026) show that even human grading of GenAI-assisted work is not a neutral, criteria-based act. Scenario-based interviews with 33 university teachers revealed grading decisions driven by person-oriented (honesty, diligence), capability-oriented (independence, GenAI skill, disciplinary mastery), relation-oriented (trust), and justice-oriented (fairness, beneficence) values — extending beyond the assignment to teachers' conjecture about the student. The study reframes the assessment question from "is GenAI use cheating?" to "how do teachers' value judgments shape grades, and are those values relevant to the outcomes being assessed?" — foregrounding validity and "two-way transparency" about how GenAI use will affect grades.

Integrity and the debate over detection

AI in assessment has intensified the integrity conversation. One strand focuses on detecting AI-generated text, while a growing body of research argues that detection is a limited, situational tool — not a strategy of first resort. Beyond Detection and Responsible Assessment argue that authenticity cannot be policed into existence; it must be redesigned, positioning AI as a declared collaborator and prioritizing authentic, process-based assessment over surveillance. **Walton et al. (2025)** ground this in evidence of **how students actually judge** their way through assessment with GenAI: scroll-back interviews with 26 students revealed a spectrum of six judgment events — from critically evaluating AI knowledge and learning through AI's limitations, to adopting ideas uncritically and misjudging AI contributions as their own. **Stamatoulis et al. (2026)** add a quantitative counterpart: across 157 students, *how* GenAI is used (evaluative integration to support understanding vs. low-verification shortcut uptake) predicted performance, while simple usage **frequency predicted neither** performance nor academic Self-Efficacy. Together these studies reframe the assessment question from *whether* students use AI to *how they judge and pattern that use*.

Bassett et al. (2026) go further, arguing detection should not be used at all: its probabilistic output cannot be independently verified because real-world text origin is unknown, and detector scores — alone or with linguistic markers, style comparisons, an LLM's claim, or student silence — do not meet the balance-of-probabilities standard integrity investigations require.

A PRISMA review of 25 studies adds a risk factor the detection debate leaves out: non-native English speakers showed a high tendency to breach integrity when struggling to write in English, so integrity expectations should be paired with concrete academic-writing support rather than enforcement alone (Balalle and Pannilage (2025)).

Assessment redesign in the AI era

The constructive question in the knowledge base's assessment literature is not "how do we prevent students from using AI?" but "how do we enable them to use it thoughtfully in contexts that mirror their future work?" This reframes assessment around:

- **Authentic and process-based tasks** that make AI use visible and assessed. Authentic Assessment — examining student performance on worthy, realistic tasks — is the leading response to AI's challenge: any task an Large Language Models (LLMs) can credibly simulate loses its validity, so authenticity must be redesigned around real-time collaboration, digital and social contribution, and

individual meaning-making. This connects to design frameworks for authentic assessment, authentic products and authenticated processes, and tool-invariant assessment of process.

- **Responsible assessment design** grounded in validity evidence (Responsible Assessment in the AI Era: Key Insights from a Future-Focused Conference)
- **Task-level AI permissions derived from assessment targets:** McCorkle (2025) shows the assessment-design work that precedes an AI policy — inventorying every task in a project, specifying what is being assessed and against which objective, and permitting or prohibiting AI per task on that basis (brainstorming and image curation allowed; composing learning objectives and slide design not). The same alignment exercise doubles as a check on the inference the assessment supports, because it forces the instructor to name the performance that a grade is meant to warrant (Assessment Validity).
- **Assessment that goes beyond the linguistic mode:** Jiang et al. (2026) define Multimodal AI assessment literacy for second language teachers as knowledge, value and competence for tasks that elicit responses across linguistic, visual, aural, gestural and spatial modes. A year-long program with 30 Hong Kong English teachers raised knowledge of assessment strategies from 3.13 to 4.15 out of 5 (partial $\eta^2 = 0.571$) and competence in supporting students from 3.05 to 3.98 (0.482), while all three value subdomains stayed flat. The teachers' own experience added two dimensions to the framework: sustaining the practice against competing curricular priorities, and mobilizing GenAI critically (Jiang et al. (2026)).
- **Coauthorship and declaration** as part of the assessment contract
- **Process-based rubric criteria that grade the interaction, not the artifact.** Oviedo and Díaz (2026) read Biggs's 3P model as three critical grading dimensions — human agency and critical supervision, dialogic scaffolding tied to Prompt Engineering, and cognitive sovereignty grounded in integrity and transparency — arguing that a finished file no longer carries information about whose reasoning produced it.
- **Production as a competency** — evaluating learners' ability to direct tools and produce professional-standard work (Knowledge, skills, attitudes, production: Competency-based education after generative AI)
- **Assessing the interaction process, not just the artifact** — the DRIVE framework (Directive Reasoning Interaction + Visible Expertise) treats the quality of a student's *engagement with GenAI* as the assessed construct. It distinguishes surface consumption from deep, reflective interaction by looking at whether students steer prompts strategically (DRI) and integrate and develop their own disciplinary ideas through the exchange (VE), grounding process-focused criteria in theories of Self-Directed Learning and cognitive engagement along the lines of the ICAP hierarchy. This makes DRIVE an example of *AI-mediated authentic assessment* — a rubric for evaluating how learners partner with GenAI rather than a detection tool.

A proposal in this literature pushes past redesign-within-the-current-frame. El Khoury and Ma (2026) argue that reform organized around preventing misconduct or detecting AI use narrows the educational imagination to control and compliance, and propose **joyful assessment** instead: assessment that is safe, emotionally responsive, empowering and supportive of student student agency, with safety as the load-bearing condition because without it emotional attunement becomes performance, empowerment becomes pressure and agency becomes risk. Their framing inverts the detection agenda — integrity becomes a consequence of designing

assessment students want to engage in rather than its starting point — and they position instructor-built AI agents (custom GPTs, Gems, Copilot Studio agents) as a low-stakes rehearsal space where students practice before judgment, with the claim that the AI organizes evidence while the instructor interprets it.

Implications for AI in education

- **Assessment and learning are inseparable:** good AI assessment should support learning (formative feedback) as much as it evaluates it.
- **Validity must be reconceptualised:** when AI can produce student work, assessments must measure processes, judgment, and authentic production, not just outputs.
- **Automation must be evaluated rigorously:** automated assessors need psychometric and fairness evaluation, not just accuracy claims.
- **Integrity shifts from detection to design:** the most robust response to AI in assessment is designing tasks where AI use is expected, declared, and scrutinized.
- **Innovative practices can address multiple problems at once.** Mesny, Roberge-Maltais & Galy (2026) argue that a set of five mutually reinforcing practices — Authentic Assessment, self- and Peer Assessment, reassessment, standards-based grading, and ungrading — aligned with the "assessment for learning" paradigm can counter the harms of traditional, summative-heavy, norm-referenced grading (superficial learning, eroded intrinsic motivation, stress and anxiety, inequity, and compromised integrity) in the generative AI era. They find uptake is uneven across fields — self- and peer-assessment dominate while the grading-focused innovations remain marginal — and urge educators to engage more actively and reciprocally with assessment and grading innovation, backed by incremental experimentation and institutional support.
- **AI-mediated assessment is diversifying.** AIvaluate shows an LLM-augmented conversational agent reduced student anxiety during performance-based assessments; Pentland (2026) finds asynchronous oral assessments offered higher engagement and were perceived as professionally relevant; graph-based ITS uses adaptive knowledge-state tracking to inform assessment.

Common Misconceptions

- **"Integrity is mainly a detection problem." Scroll-back interviews with 26 students** reveal that students judge their way through assessment with GenAI along a **spectrum**, and across **157 students**, *how* GenAI is used — **evaluative integration to support understanding versus** substitution — predicted the outcome. The mode of use separates students more sharply than the presence of use.
- **"Non-native English speakers are the cheating risk."** A **PRISMA review of 25 studies** adds a risk factor the detection debate leaves out: non-native speakers showed a **high tendency to breach integrity when struggling** with the language demand. That is a language-support problem misread as an honesty problem.
- **"A policy that forbids GenAI settles the question."** Students report a spectrum of judgments rather than a rule-following pattern, so a rule that does not engage the evaluative reasoning students are already doing will not be followed consistently.

Evaluative Judgment

> **Evaluative judgment** — the capacity to make sound judgments about the quality of one's own work and the work of others, against criteria one can reason about rather than recite. In the generative AI era it has moved from a desirable graduate attribute to a load-bearing capability: when a tool can produce plausible finished work, the capability that distinguishes a competent learner is the ability to appraise that output — to judge what is good, what is wrong, what to accept, what to reject, and why. This makes evaluative judgment a legitimate object of Assessment in its own right, and the practical pivot for moving institutions from detection toward validity-centered and authentic assessment design.

Questions to Consider

- Think of something you can judge well. How did you learn that judgment — explicitly taught, or absorbed by making and comparing — and what does that imply for how it should be assessed?
- A rubric can be applied mechanically or understood. If a student follows criteria correctly but cannot say why one piece of work beats another, which capability has the assessment actually measured?
- When a language model drafts a plausible solution, the learner's remaining work is largely judgment: what to keep, what to fix, what to discard. Is that a diminished task, or a more demanding one than producing the draft?
- A student can accept an AI suggestion because it reads well, or because it survives their own scrutiny. From the outside the submission may look identical — what would let an assessor see the difference?
- A multisite experiment found that direct AI feedback produced the largest revision gains but risked passive outsourcing of judgment. What does that trade-off suggest about how you would design feedback to build rather than bypass judgment?
- Peer and AI review can train calibration, but both can become performative. How would you design assessment so that exercising judgment is required rather than performed?

Introduction

Assessments that ask students to produce work presume they can tell good work from poor work, first in others and eventually in their own. That presumption is no longer reliable: when generative AI can generate competent prose, code, and analysis on demand, the ability to *produce* a product is a weak signal of learning, while the ability to *judge* a product is a strong one. Evaluative judgment names that ability, and the knowledge base's assessment scholarship keeps arriving at it when asking what remains assessable and worth assessing. It sits where Feedback, Formative Assessment, and Self-Regulated Learning meet, because judgment is developed by comparing work against standards and acting on the difference, and it is what makes genuinely critical engagement with AI output possible rather than aspirational.

Xu, Lu and Abdi (2026) argue from a twelve-study scoping review that AI writing scores reproduce a narrow construct: they track checkable surface features and under-weight organization, coherence and argument, which are the dimensions a judgment of writing quality turns on.

What the construct is

Evaluative judgment is the capacity to appraise quality — one's own work, peers' work, and increasingly the work of an AI system — using criteria one can reason about rather than recite. Three features distinguish it from adjacent ideas.

- **It is about quality, not correctness.** Answering correctly requires knowledge; judging whether an answer is good requires standards a generator cannot supply on the learner's behalf.
- **It is developed, not transmitted.** Judgment grows through repeated acts of comparison — against exemplars, explicit criteria, and peers' differing approaches — which is why exemplars, calibration exercises, and peer assessment are its natural pedagogies.
- **It is domain-situated.** It is exercised inside a discipline's standards of evidence and argument, so it cannot be assessed generically any more than transfer can be assumed.

It is closely related to, but narrower than, authenticity in assessment: authentic assessment asks whether a task resembles worthwhile real-world work; evaluative judgment asks whether the learner can tell good work from poor work. Self-Assessment appraises the learner's own work, competence, or progress against criteria, whereas evaluative judgment extends that appraisal to peers' work and to the output of an AI system as well.

Why generative AI made it central

Four arguments converge.

- **The product stops being evidence.** Completion of a task no longer demonstrates the capability the task was designed to certify, because a tool can complete much of it. What remains is the reasoning that produces, checks, and accounts for the product — judgment, in short.
- **It is the capability that governs AI use.** Deciding whether an AI suggestion is worth accepting, adapting, or rejecting *is* evaluative judgment applied to machine output. Courses that cannot make it visible cannot tell responsible use from substitution, which is why integrity scholars increasingly treat critical AI use as an assessable outcome rather than a rule to be policed.
- **It is the pivot from enforcement to design.** Where prohibited use cannot be detected, Teichmann (2026) names cultivating evaluative judgment among the three design strands that relocate institutions from detection-led enforcement to validity-centered assessment — because where the institution cannot detect, the capability that survives inspection is whether the student can account for the work and its quality.
- **It converts disclosure from confession to evidence.** When a task asks students to explain what they used AI for, which suggestions they accepted or rejected, and how the final submission reflects their own judgment, the declaration becomes a demonstration of judgment rather than an admission to be interpreted punitively — which is what lowers the cost of honesty that otherwise drives disclosure underground.

- **Judgment is cultivated by composed constraints, not by removing them.** Elkington (2026) argues that generative constraints such as a short visual draft before a final artifact, or a limit of three interview clips, pace cognitive work and make judgment visible, because constraints create the moments in which appraisal is practiced.

A further layer concerns the *source* of a judgment, not only its content. AlGhamdi (2026) gives that layer a sharper vocabulary: his 13 Saudi computing students rendered two independent judgments within a single evaluation event — whether the feedback was useful, and whether its source held authority to grade. They all accepted ChatGPT's rubric-based feedback as clear and specific while overwhelmingly reserving the grade for the instructor ("I agree with it, but with one condition, that the doctor checks the feedback"), suggesting evaluative judgment in AI-mediated assessment must now include reasoning about evaluative authority itself, not only about the quality of the feedback received.

Sharma (2026) gives the construct its strongest placement in the integrity literature. Extending Eaton's (2023) postplagiarism framing from an ethical orientation into assessment design, he argues that detection- and verification-based models of integrity are misaligned with work in which human judgment and machine generation are entangled. He reframes integrity as a pedagogical practice enacted through evaluative judgment — the learner's capacity to weigh options, justify academic choices and assume responsibility under epistemic uncertainty. His four practices (annotated decision trails, verification and accountability, oral defense and dialogic accountability, draft differences with version history) make that judgment visible as evidence rather than inferring it from the artifact. He separates judgment from the constructs it is often collapsed into: reflective practice considers one's thinking retrospectively, Metacognition is the awareness and regulation of cognitive processes, whereas judgment evaluates options against standards and accepts consequences under uncertainty. He also names the failure mode this page tracks — requiring documented reasoning risks "the replacement of one compliance regime with another", since judgment as evidence "remains relational and situated rather than mechanically verifiable".

Evidence: how judgment develops, and what AI does to it

The knowledge base's collaborative and assessment literature supplies convergent evidence that evaluative judgment is *learnable*, *displaceable*, and *designable* — and that AI cuts both ways.

- **Comparison-based training measurably builds it.** In a 14-week study with 28 pre-service teachers, AI-generated strong, average, and weak exemplars anchored iterative comparison of students' drafts against reference points; evaluation focus expanded from surface language features to content, organization, and coherence — but the reasoning stayed thin, with example-based justification doubling while the most sophisticated comparative reasoning remained rare. Judgment can be scaffolded into existence; it does not appear on demand, and the quality of the reference points matters.
- **Feedback design decides whether agency survives.** A multisite, cluster-randomized field experiment with 1,176 first-year undergraduates across 48 sections compared four feedback conditions for scientific argumentation: peer-only, direct GenAI, reflective GenAI (self-evaluate then critique), and hybrid (self-evaluate + peer + GenAI). The **hybrid condition produced the largest argument-quality gain**; direct GenAI feedback risked passive uptake — students outsourcing evaluative judgment to the system — while reflective and hybrid designs preserved

epistemic agency by forcing the student to evaluate their own work first. The authors' core finding is that GenAI's educational value depends less on AI access than on whether the feedback environment preserves agency, judgment, and ownership during revision.

- **A feedback tool can scaffold judgment while teachers keep the relational part.** With 21 higher-education teachers using PolyFeed, the model surfaced omitted components (20 of 21 had skipped "Meeting Learning Objective") and 12 rewrote the ChatGPT text, clustering in the student–teacher relationship dimension (Aldino et al. (2026)).
- **Feedback source shapes which judgment dimension develops.** In a doctoral statistics case study, ChatGPT-4o gave procedural guidance but could not flag a wrong data file or a misapplied test, while peer dialogue caught the erroneous data in real time and forced justification of the method choice (Xie et al. (2025)).
- **Structured peer-and-AI review scales calibration.** The PAIRR model (Sperber et al., 2025) combines peer review with AI review and structured reflection, and was tested in the largest study of students' use of AI feedback to date (654 students, ten writing courses). It treats the *comparison* between one's own judgment, peers', and AI's as the training ground, positioning evaluative judgment as an explicit learning outcome rather than an implicit by-product.
- **AI feedback helps only when literacy already exists.** A conceptual framework from feedback-literacy leaders (Boud, Dawson & Yan) analyses feedback across eliciting, processing, and enacting, using two contrasting IELTS-with-ChatGPT cases: a student with low feedback literacy used a vague prompt, received generic output, and trusted or over-copied it, while a literate student used AI critically and learned. GenAI lowers the cognitive and emotional barriers to seeking feedback but can itself be hallucinated, biased, or generic — which is why teachers are argued to model evaluative planning and train judgment, not just prompting.
- **Sustainable judgment, not momentary feedback, is the gap.** A scoping review of authentic assessment (Zhan, Boud & Du) found AI-formative feedback abundant but **sustainable feedback** — transferable to future contexts — present in only 4 of 23 formative studies. Feedback that closes the current task while leaving the learner unable to judge future work is the evaluative-judgment failure in its clearest form.
- **Borrowed judgment: receiving an interpretation without practicing interpretation.** Åhman and Thorén (2026) name the failure mode this page treats as the learner's remaining work. Where a study tool generates the summary, the structure and the prioritization, the learner is served the *products* of reasoning while skipping the interpretive struggle that produces judgment — their "borrowed judgment". The distinction matters because it is not a question of output quality. An AI study tool can be fully cited to the student's own uploaded sources and still preconfigure relevance, so judgment is exercised only where the system requires the learner to take a position, confront competing interpretations, and explain their choice.
- **Critiquing generated drafts built the educators' judgment.** Paula et al. (2026) found that eight course coordinators' assessment literacy grew as they critiqued a GPT-4.1 tool's generated rubrics and timelines against disciplinary standards, while all eight refused end-to-end automation — the tool strengthened academic judgment rather than replacing it.

- **Assessment can be designed to reward judgment instead of output.** The response-region model formalizes why: redesign lowers the payoff from hidden outsourcing and raises the value of visible reasoning, explanation, and critique. Asking students to explain which AI suggestions they accepted and rejected turns the decision itself into assessable evidence.
- **The institution's own judgment lacks the criteria it asks students to meet.** Munoz et al. (2026) rated the probative value of 1,855 evidence items across 1,162 generative-AI misconduct allegations and found that evidence quality bore no reliable relationship to case outcomes, because no stage of the procedure set a minimum evidentiary threshold or required investigators to weigh probative value before progressing an allegation — panels weighed evidence through unstructured professional judgment. Detector output was the weakest category in that corpus (standalone detector outputs wholly low in credibility), and Hadra et al. (2026) show the instrument cannot establish the fact a finding asserts — macro accuracy of 0.69 and 0.61 across 192 texts, near-total failure on hybrid human–AI writing, and a borderline bias concern for EFL writers — which is why the authors' own recommendation is human judgment, clearer policy and better-specified tasks rather than surveillance. Better-specified matters twice over: Wright (2026) argues that rules written by platform identity rather than function are over-inclusive by definitional accident, sanctioning a student who did not do the thing the rule was designed to prevent, so the assessor's judgment has to be applied to what a tool did rather than to which platform was used. Judgment exercised without shared criteria cannot be taught, calibrated or audited — the consistency problem this page reports for students, arriving at the level of the institution. Evaluator judgment also carries a measurable direction of its own: five admissions officers separating 50 human from 50 AI admissions essays reached AUC 0.70 (95% CI [0.65, 0.75]), and their quality ratings fell as perceived AI-likelihood rose, an association that survived adjustment for machine-rated quality, actual provenance and applicant characteristics (−0.109, $p < .05$). Because nobody screened the submissions, that unaided judgment was the entire enforcement mechanism, and each flagged essay carried 1.5 percentage points less admission probability, 2.6 once essay quality was held constant (Isley, Gaebler and Goel 2026).
- **Classroom-level proxies for judgment are being proposed.** Austin (2026) adds two behavioral signals to a redesigned assignment sequence: the UnBlooms™ *Discernment Rate*, the share of AI outputs a learner interrogates, challenges or revises rather than accepts, and the *First-Pass Acceptance Rate*. Neither is validated — both are offered as cheap per-assignment diagnostics — but they make the construct observable inside ordinary grading, where a near-zero discernment rate across several assignments reads as a task-design signal rather than an individual deficit.
- **Judgment registers when wired to revision, not merely present.** In 67 pre-service teachers designing lesson plans with GenAI, explicit evaluation was near-absent in the lower-quality group (0.67 vs 0.00); what separated quality was a bidirectional evaluation–revision cycle (CE → RE $Z = 2.80$, RE → CE $Z = 2.50$) and a revision self-loop (RE → RE $Z = 4.24$) (Fang et al. (2026)).
- **Instructors' criteria can be externalized by revising AI output.** Tang et al. (2026) inferred reusable validation rules from 16 instructors' edits of LLM-generated programming feedback and raised alignment with their pedagogical intent from 57% to 91%, making tacit criteria inspectable rather than leaving them unstated.

How misuse displaces judgment

The clearest risk is displacement, and it is evidenced in the feedback literature rather than only theorized. When the tool supplies the rubric, the feedback, and the monitoring, the learner's metacognitive and evaluative practice is displaced rather than supported — the assessment becomes a performance of judgment the student never exercised, the same failure mode as cognitive offloading expressed in the assessment register. Direct GenAI feedback in the multisite experiment pushed toward exactly this passive outsourcing. Grading pressure compounds it: where self-assessment or reflection on AI use is itself graded, students can produce the reflection the rubric wants rather than the reasoning, so genuine judgment requires making the exercise consequential — a decision that shows up in later work, an oral explanation, or a documented rationale that is itself examined.

The same reasoning admits a structural version. Åhman and Thorén (2026) name **patterning** as the developmental work of organizing complexity into structures a learner finds meaningful, and argue that a system which pre-sorts relevance removes the conditions that work requires. Their term for the result is **borrowed judgment**: the learner appraises material the system already structured, so judgment is performed but never earned. The paper is a theoretical analysis with no data of its own — the Tentaklar platform illustrates the mechanism rather than testing it — so the failure mode is argued from design, not observed in learners.

Displacement has a teacher-side version, and it is what turned several writing professors against outsourcing marking entirely. Five of the twenty-four said marking is how a teacher comes to understand their learners, so delegating it costs that understanding rather than only the hours (Wu and Lam (2026)). Eighteen of the twenty-four treated human judgment as what catches the tool's errors and owns the accountability for them.

Implications for practice

- **State it as an outcome.** If appraising work quality — including AI output — is what matters, write it into the learning outcomes and assess it, rather than leaving it as a by-product of the task.
- **Assess the decision, not only the artifact.** Ask students to justify what they kept, changed, or rejected; this turns the thinking into evidence and makes substitution visible without surveillance.
- **Name the judgment routine.** O'Byrne's Agency Check — Credible, Relevant, Acceptable, Nuanced — asks whether output is accurate, fitting, serviceable, and carries stance and voice; in a semester-long study, final artifacts from the most and least judgmental students looked deceptively alike (O'Byrne, 2026).
- **Use exemplars and calibration deliberately.** Comparative judgment against strong, average, and weak exemplars is the mechanism the evidence supports, and AI makes generating those exemplars cheap — one of its clearest pedagogical uses.
- **Prefer hybrid and reflective feedback over direct output.** Self-evaluation before AI critique, or self + peer + AI, preserves the Learner Agency that direct AI feedback erodes; design the feedback environment rather than just adding a tool.
- **Build toward sustainable judgment, not momentary fixes.** Feedback that cannot transfer to the next task trains nothing durable.

- **Pair it with process and orals.** Process artifacts and short oral explanations show judgment in action where a final product cannot, which is a core reason AI-era assessment redesign relies on them.
- **Make retained judgment visible with comprehension-debt probes.** Mahmoud (2026) defines four cross-cutting obligations — explain, verify, modify, and account — that make retained competence visible at every level of AI integration, and proposes delayed change requests, code walkthroughs, independently designed tests, defect localization, and live debugging as probes that compare what was produced with what can later be demonstrated. Under agentic capability the assessment target moves to supervision — task contracts, permission boundaries, sandboxes, evaluation harnesses, diff review, rollback, and human accountability — shifting assessment from visible authorship toward visible judgment.

Common Misconceptions

- **"Evaluator error is random noise." Evaluator judgment carries a measurable direction of its own**: five admissions officers separating **50 human from 50 AI admissions essays** reached **AUC 0.70**, meaning they could distinguish the sources only weakly — and because nobody screened the submissions, that **unaided judgment was the entire enforcement mechanism**, with each flagged essay carrying **1.5 percentage points less admission** probability. A weak signal became a real penalty.
- **"Peer and AI review are substitutes."** The PAIRR model (Sperber et al., 2025) **combines peer review with AI review** to structure calibration. Combining them is the design, which implies neither alone supplies it.
- **"Judgment quality is a property of the judge."** The admissions finding locates the problem in the arrangement — an unvalidated judgment applied at consequence with no screening stage — rather than in the individuals' ability.

Feedback

> **Feedback** — information provided to a learner about their performance or understanding that is intended to close the gap between current and desired performance. In AI in education, feedback has become a central and rapidly transforming theme: AI systems now generate, deliver, and even teach students how to use feedback, reshaping every stage of the feedback process.

Questions to Consider

- Feedback is often imagined as information handed to a learner, but research argues it only 'counts' as feedback when the learner makes sense of and acts on it. If feedback is a relationship rather than a message, what changes about how we should deliver it?
- Students' perception of whether feedback came from an AI or a human can change how much they learn from it. Why do you think the *source* matters so much — and what does that imply for AI-generated feedback in your context?
- Immediate feedback can be a trap: the 'correct-answer trap' shows that students who simply copy corrections learn less. When does instant feedback help, and when does it short-circuit the very learning it's meant to support?
- Research even found that a well-designed sequence of feedback — encouragement, then hints, then the answer — designed to build autonomy actually *harmed* learning despite boosting engagement. If students feel good about feedback that makes them learn less, what should we optimize?
- Feedback is described as a system with parts: the feedback loop, quality of provision, the learner's uptake capacity, and the assessment context. If you were trying to improve feedback in your own course, which part would you fix first, and why?

Introduction

This is the umbrella concept for the knowledge base's feedback-related ideas. Feedback sits at the intersection of assessment and learning: without feedback, assessment measures performance but does not improve it; with effective feedback, assessment becomes a learning event. The knowledge base treats feedback as a **system** with multiple facets — the quality of the feedback itself (AI Feedback Quality), the loop through which it closes the learning gap, the learner's capacity to use it (Feedback Literacy), and the assessment contexts in which it operates (Formative Assessment, Peer Assessment, Automated Assessment).

- **Yilmaz et al.** show that students' perception of the feedback *source* (AI vs human) shapes self-regulated learning from GenAI feedback — a crucial qualifier for feedback effectiveness claims.
- **Nazaretsky et al. (2025)** isolate the source from the content: 472 EPFL students rated content-comparable human and GPT-4.0 feedback on their own work, first blind and then again after the source was disclosed, and most could not reliably tell the two apart (287 of 472 guessed correctly). Once the label was revealed, ratings of the AI variant fell and of the human variant rose — significantly for Genuineness ($p < .01$) — and provider credibility separated cleanly (human μ

= 3.28 vs. AI μ = 2.25, Cohen's d = 0.57). The bias attaches to the provider rather than the text, since the two variants were comparable on correctness and cognitive quality. Pérez-López et al. (2026) carry feedback credibility through to learning: among 230 business students after an AI-supported essay, credibility predicted perceived learning, with perceived competence and human-like empathy as its antecedents.

The feedback system

Feedback is best understood not as a single event but as a connected system of interacting parts, each of which the knowledge base documents as its own concept:

- **The feedback loop** — the mechanism through which feedback closes the gap between current and desired performance; the cycle of performance → feedback → revision → improved performance that drives learning.
- **AI Feedback Quality** — the accuracy, usefulness, timeliness, and pedagogical value of feedback generated by AI; the provision side of the system.
- **Feedback Literacy** — the capabilities and dispositions students need to understand, evaluate, and act on feedback; the uptake side of the system.
- **Formative Assessment** — the assessment context in which feedback is used to improve learning while it is still in progress, rather than merely to judge it.
- **Peer Assessment** — feedback exchanged between Learners, increasingly augmented by AI and a site for developing feedback literacy.
- **Automated Assessment** — AI-driven scoring and feedback, from automated essay scoring to confidence-aware short-answer grading.
- **The parts trade off against each other.** Designing feedback means choosing among usability, sources and sustainability rather than maximizing all three; Pedlow et al. (2026) treat sustainability as the pole that must not depend on any single individual, resource or institutional condition.

The feedback loop

The feedback loop is the cyclical process where AI systems assess student work, deliver feedback, observe the student's response, and adapt subsequent instruction. AI-mediated feedback loops operate at multiple timescales:

- **Immediate feedback:** Automated grading systems and AI tutors provide real-time correction during Problem Solving. Correct-answer trap research shows that immediate feedback can short-circuit learning if students simply copy corrections. Generating that immediate corrective feedback with LLMs inside a tutor is feasible but imperfect: across 6,926 logged transactions in the Apprentice Tutor College Algebra platform, Reddig, Arora & MacLellan (2025) found GPT-4 produced hints targeted to the student's specific error ~66% of the time, yet ~35% of hints were too general, incorrect, or prematurely gave away the answer, and LLM-based automated quality checks misaligned with human judgment — reinforcing that unvetted AI feedback in the immediate loop carries real short-circuiting risk.

- **Assignment-level feedback:** Formative Assessment systems and AI feedback quality research examine whether AI-generated assignment feedback improves subsequent work. Sequenced feedback studies test whether the order of feedback matters.
- **Course-level loops:** Learning analytics dashboards and educational platforms aggregate feedback across assignments to identify patterns and recommend interventions.

The effectiveness of a feedback loop depends on feedback quality — accuracy, specificity, timeliness, and actionability. AI peer feedback systems add a social dimension to the loop.

The human in the loop: feedback loops are not purely automated — teachers often mediate AI-generated feedback before it reaches learners. Studies of AI feedback tools for teachers (e.g., the PolyFeed tool combining an ML detector with an Large Language Models (LLMs) rephraser) find teachers use professional judgment to **accept, edit, or reject** AI suggestions — an "assist but verify" pattern — and systematically moderate exaggerated praise and generic suggestions to protect authenticity and voice. The **relational/affective dimension** of feedback (student–teacher relationship, encouragement) most strongly resists AI delegation, suggesting this part of the loop remains inherently human. This human-in-the-loop mediation connects to Human-in-the-Loop and to Teaching. - **The relational penalty is measurable, and separable from quality.** In a three-arm RCT with 287 writers, AI and instructor feedback raised revised-essay quality equally (d = 0.60 and 0.59), but instructor feedback raised intrinsic motivation through perceived relatedness (Liu & Shi (2026)).

Luo and Eaton's policy review sharpens the same point: only 14 of 50 top-ranked universities had specific guidance on teachers' AI use for feedback, and students described undisclosed AI feedback as "disingenuous", making transparency and consent preconditions of ethical practice rather than courtesies (Luo & Eaton (2026)).

LearnLens turns that mediation into a mechanism: it treats a teacher's edit as a signal of dissatisfaction rather than a correction, spending additional compute on deeper reflection instead of returning the fast answer, and its teachers' median time per assignment fell from 10–30 minutes to under five (Zhao et al. (2025)).

The relational reading cuts deeper than substitution. In workshops with 12 students and 18 educators, Bearman et al. (2026) found students treated AI as an additional but flawed source, weighing it against rubrics, lecture notes, discussion boards and educator comments, and using it as a holding pattern when human responses were slow; one pasted thin educator comments into a chatbot to work out what to do next. AI's presence changed relations rather than merely adding comments, to the point that one student stopped trusting peer discussion-board feedback as probably AI-written. The authors therefore propose humans-as-the-loop: people helping people build stronger feedback relationships over time, in place of oversight of machine output.

Winstone et al. (2026) reframe GenAI feedback as matters of care — an ethical, relational practice rather than information transfer — and name a safe-space paradox: the tool's reduced personal risk may forgo priming students for the friction of professional feedback encounters.

How AI transforms feedback

AI changes feedback in three consequential directions, each raising the stakes of the other facets:

- **Volume and immediacy.** AI can generate feedback instantly and at scale, dramatically increasing how much feedback students receive. Multi-site GenAI feedback studies and AI feedback in higher education document AI feedback experienced as comparable to teacher feedback in acceptability and supportiveness. A PRISMA-guided systematic review of 42 empirical studies (2023–2025) corroborates this scale benefit — LLMs can accelerate grading and deliver rapid, personalized feedback at scale, especially in large or higher-education cohorts — while cautioning that such feedback is sometimes too generic or misaligned with the assigned grade, and that reliability slips on longer, multilingual, or nuanced tasks (Can ChatGPT Replace the Teacher in Assessment? A Review of Research on the Use of Large Language Models in Grading and Providing Feedback).
- **Personalization is a bias vector.** Holding eighth-grade essays constant, four LLMs over-praised and withheld critique for students marked by race, language, or disability — so which student attributes feed a feedback system is a fairness decision, not a neutral one (Tan, Phalen & Demszky (2026)).
- **Evaluation demands on the learner.** Because AI feedback can be inaccurate or hallucinated, students must judge whether to Trust and act on it. This is where Feedback Literacy and Trust Calibration become decisive: Mendoza et al. (2026) show that only feedback-literate students convert AI feedback into Self-Regulated Learning gains, while the LLM fallacy captures how students may over-credit AI feedback to their own competence.
- **Feedback literacy is built by use, not demographics.** In 486 EFL undergraduates, only frequency of AI tool use predicted AI feedback literacy ($\beta = 0.29$) — not major or year of study — so scaffolding access to AI-mediated feedback is an equity question as much as a design one (Liu & Deris (2025)).
- **Lab approval is not semester use.** All 18 students reacted positively to the GenAI explanation function in lab sessions, yet only half used it during the term, citing mismatch, irrelevance, and redundancy when educator feedback was already clear (Jin et al. (2025)).
- **Trust and care, not accuracy, bound uptake.** Seventeen EFL students granted an AI writing assistant high expertise yet doubted its trustworthiness over data handling and rated its goodwill lowest, authorizing it only for broad language concerns; several also found its volume of suggestions unmanageable (Serpil & Mor, 2026).
- **Task-level suitability: sorting feedback by epistemic status.** Venetsanos (2026) argues that the frameworks the field relies on — Hattie and Timperley's levels, Boud and Molloy's design principles — explain *where* feedback operates in learning but not whether a given feedback task involves rule-checking, factual verification, or interpretive judgment, and that it is the second distinction that decides whether automation is defensible. The proposed tripartite split is low-level structural and presentational feedback (formatting, referencing, grammar, sentence-level clarity — rule-based against explicit standards and safely automatable), intermediate-level factual and procedural verification (whether a calculation used a specified method correctly, whether a stated

fact matches authoritative references — comparison against established knowledge, not judgment of reasoning), and high-level critical evaluation and synthesis, where judgment is interpretive and must stay human. The levels are dimensions rather than a ladder: one calculation can be correctly presented, arithmetically wrong, and methodologically inappropriate at the same time, and can attract verification, process feedback and self-regulation feedback together. The framework's sharpest boundary case is clarity: sentence-level clarity is surface-level, but *argumentative* unclarity often signals incomplete conceptual grasp, so flagged instances should escalate to human review rather than being corrected as prose — fixing the writing would leave the actual problem untouched.

- **Role-aware feedback.** Yaşar et al. (2026) showed that prompting the same LLM to evaluate the same student artifact under different roles — instructor, peer reviewer, grant reviewer — produced qualitatively distinct feedback: instructors were encouraging and process-oriented, peers supportive and conversational, grant reviewers formal and outcomes-oriented. These differences were epistemic, not merely stylistic, foregrounding different aspects of design practice — evidence that role-aware prompting can generate role-sensitive evaluative feedback rather than a single generic response.
- **Feedback type matters more than feedback density.** An eight-week adaptive stochastics study (194 students) found directive, informative and transformative feedback were taken up differently, and transformative feedback contributed to cognitive overload — so feedback design should match type to the learner's phase rather than maximize volume (Mejeh & Fromm (2026)).
- **Feedback utility vs. evaluative authority.** AlGhamdi (2026) shows students can simultaneously accept AI-generated feedback as useful and reject AI as the appropriate grader — separating *feedback utility* (the informational value of surface-level feedback) from *evaluative authority* (who may decide the grade). In a transparent post-assessment design, Saudi computing students treated these as analytically distinct judgments, valuing ChatGPT's clarity for revision while reserving grading authority for the human instructor and articulating the dialogical, institutionally-weighted reasons why. The finding extends Feedback Literacy beyond judging feedback quality to reasoning about evaluative authority itself, and suggests transparency about AI involvement can make feedback an object of critical reflection rather than passive acceptance.
- **The revision's stance is an outcome, not just its quality.** Feedback research usually asks whether a revision improved the text. Zhao and Ji (2026) ask what rhetorical stance the revised text takes, coding 168 EFL argumentative essays with Appraisal Theory across first drafts, revisions after peer feedback, and ChatGPT-4 revisions of the same drafts. Engagement language was equally frequent in all three, but differently configured: peer-feedback revisions became more contractive (more Counter and Endorse, less Entertain), while the AI revisions kept a more balanced Contract/Expand mix. Neither is better writing — the point is that the two revision routes leave the argument in a different dialogic position, which makes stance itself something a feedback conversation can name and a writer can choose.
- **An explanation can be persuasive and still unfaithful.** Bueno et al. (2026) found that removing the sentences an LLM rationale ranked most influential barely moved a rubric score, while SHAP-

selected sentences shifted it reliably and transferred across model families, so a fluent justification is not evidence that a score rests on it.

- **Feedback literacy as a training goal.** Rather than only providing feedback, AI tools are increasingly designed to *teach* students to use feedback — reframing automated feedback tools as literacy-building instruments, framing GenAI as an enabler of feedback engagement, and using GenAI critique tasks to build psychological, feedback, and AI literacies together.
- **Feedback literacy and calibration are separable levers.** With 120 undergraduates, a Feedback Literacy Script (Filter–Reason–Act–Check) raised writing quality, effective uptake, and deep revision, an Assessment-Performance Calibration Activity improved self-assessment accuracy and cut overconfidence, and combining them produced the largest writing gains and the strongest retention after AI support was withdrawn (Dai (2026)).
- **Clarity is not effectiveness.** LLM-rewritten Python error messages were rated significantly more readable and less cognitively demanding than standard interpreter output, yet produced no significant gain in fix rate, attempts, or time-to-fix (Moraru, Biswas & Gadiraju (2026)).

What makes feedback effective: calibration evidence

Ngai & Gilbert (2026) provide a clean experimental result on feedback design with direct relevance to AIED: **veridical, immediate, trial-by-trial feedback tied to a learner's own prior prediction is what changes behavior — prediction or beliefs alone are not enough**. In their four-group design, feedback combined with a preceding performance prediction improved calibration and behavior, while predictions without feedback did nothing, and adding an explicit over-/underconfidence label added nothing further. LLMs can also serve as calibration partners in this process: Yaşar et al. (2026) found that after rubric refinement, LLMs demonstrated greater consistency than some human raters in applying performance thresholds — useful for norming sessions and formative peer feedback environments, where the model helps calibrate evaluative judgment rather than replace it. This aligns with the knowledge base's feedback-system view: feedback's power lies in closing the gap against a learner's *own* estimate (the provision–uptake pairing), and effective feedback should be immediate, accurate, and explicitly connected to what the learner predicted — a design principle for AI feedback systems and Feedback Literacy training alike.

Effort, however, is not automatically the missing ingredient. In a preregistered between-subjects experiment with 302 US adults learning introductory Python, Asher, Gold & Carvalho (2025) paired personalized Claude Sonnet 3.5 explanatory feedback with a structured three-step self-explanation prompt — for each incorrect code section, what the correct code does and why the learner's own attempt failed — and the added reflection bought nothing. Reflective Practice participants spent 4.1 minutes reviewing feedback against 2.1 minutes in plain Practice ($t(267) = 11.30$, $p < .001$), which left room for only 2.0 practice problems instead of 3.4 ($t(267) = 8.20$, $p < .001$). Each problem was worth the same either way (Reflection × problem-number OR = 1.03, $z = 0.23$, $p = .486$), so Practice ended with higher mastery, 79% versus 65% ($d = .41$), and never fell behind on near-transfer, far-transfer, or code-evaluation items. Reflection also failed to deliver the metacognitive benefit it targeted: judgments of learning did not differ across arms, and the practice conditions were better calibrated (underconfident by 11 points, against video watchers 20 points overconfident, $d = -.93$) and reported less distraction ($d = -.80$) than reflective learners, whose reflections averaged only 35 words. The authors' reading is that the AI feedback had already supplied the Scaffolding

that self-explanation normally adds — a message that names the error, explains the correct approach and describes the underlying concept leaves little for a reflection prompt to do. Writing reflections while still learning unfamiliar syntax also competed directly with the varied repetition that builds transferable skill. This locates a boundary condition for Desirable Difficulties and Productive Failure on the processing-depth axis: effort pays when it drives additional retrieval, application or comparison, and is redundant when the learner is already receiving a personalized explanation of their specific error. It also bears on how feedback quality interacts with uptake. The more elaborated and targeted the feedback, the narrower the space for an added layer to add value, which shifts design attention from deepening one episode to spending scarce practice minutes on volume, problem variability, and timing reflection to moments such as a detected plateau. The study tested a single unvetted enhancement, and the authors note that these variants remain open.

- **Focus and adaptivity are separable dimensions of feedback.** Annotation of teacher and LLM comments in three university writing courses with seven feedback focus types shows that most models cover nearly every type while none matches the teacher's distribution across them, and none shifts its focus across draft stages the way an expert instructor does (Almousa et al., 2026).
- **Aggregate gains can hide offsetting shifts.** Three months of WISE Agent feedback with 260 Chinese sixth-graders moved no total critical-thinking disposition score ($t=-0.854$, $p=0.394$), yet Truth-seeking rose ($p<0.001$) while Cognitive Maturity fell ($p=0.019$) — a dip the authors read as students recalibrating overestimated understanding. (Zhu et al. (2026))

Feedback across assessment contexts

The knowledge base's feedback research spans the full range of assessment contexts, each with distinct feedback dynamics:

- **Formative feedback** is the canonical site of feedback-for-learning — formative assessment feeds self-regulated learning through feedback that arrives while learning is still in progress (automated formative assessments, feedback enactment).
- **Summative feedback** is the feedback attached to summative assessment — end-of-unit tests, oral exams, and proctored/closed-book examinations. In the AI era, the summative setting is where AI resistance matters most (see Summative Assessment): feedback on a proctored oral exam or closed-book assessment tests genuine learning, whereas feedback on AI-assisted homework can be inflated. Oral assessments reframe the feedback moment as a live, interactive dialogue — feedback becomes immediate, conversational, and inseparable from the assessment itself, which is precisely why they resist AI substitution.
- **Peer feedback** adds a social layer — peer feedback develops feedback literacy and is increasingly AI-augmented (AI peer feedback, GenAI in EFL peer feedback). Yet peer feedback is only as good as its actual delivery: in a semester-long field experiment, under two-thirds of students assigned peer feedback received no textual feedback at all, and much of what was delivered was non-targeted praise — so when individual GPT-4 feedback replaced unreliable peers, students sustained the highest participation and posted the largest content learning gains (Geschwind et al., 2026), evidence that the AI's edge is a *reliability* advantage rather than inherent superiority.

- **Prompt scaffolding turns GenAI into a feedback facilitator.** Chang et al. (2026) found that students given structured prompts (context, objective, role) for peer feedback produced more explanations and suggestions, and only that group excelled on rebuttal data and on addressing the opposing view.
- **Automated feedback** scales delivery — automated scoring and feedback from essay scoring to short-answer grading. Arthur (Yin et al. 2026) extends this to unstructured quantitative problems: a per-question XGBoost diagnosis backbone infers rubric-labeled mistakes from students' submitted numerical answers to Engineering Economics Calculated Formula Questions and turns them into natural-language feedback, while a dialogue-based scheme requests intermediate answers only when confidence is low — balancing feedback accuracy against the collection burden on students.
- **Automated writing evaluation is a delivery-side tool with a measurable cost.** A review of 50 empirical studies (2019–2024) found that automated writing evaluation improved grammar, punctuation and sentence construction in 25 studies and reduced teachers' mechanical correction workload in 15, freeing time for argument, coherence and organization. Gains held only where the tools sat inside structured drafting and revision cycles rather than as stand-alone aids. Heavy reliance on them was linked to weaker critical thinking and Creativity, and the tools reproduced standardized English norms that EFL users reported as misaligned with their rhetorical traditions (Gres et al., 2026).

A key cross-context insight is that **the reliability of feedback depends on the integrity of the assessment it is attached to**: feedback is only as trustworthy as the measure it responds to. In the AI era this pushes educators toward authentic and AI-resistant summative formats where the feedback a student receives reflects genuine learning rather than AI-assisted output.

The "assessment for learning" paradigm reframes feedback as an overarching philosophy rather than a component. Mesny, Roberge-Maltais & Galy (2026) synthesize the wider higher-education literature to frame formative, ongoing, and individualized feedback as central to that philosophy, balancing formative with summative purposes and foregrounding student agency, self-AI Regulation in Education, and metacognitive skill. They note, however, that in management education feedback-rich practices remain unevenly adopted: self- and peer-assessment (a site of peer feedback) dominate the literature, while reassessment — which uses feedback-driven second chances to improve learning — is virtually absent.

- **Demonstrated actionability is not enacted actionability.** In a scoping review of 421 studies applying NLP to open-ended student evaluation of teaching comments, 61.3% produced output at the level of a demonstrated result or stronger, but only 11.6% showed evidence that intended users evaluated or used it (Eicher & da Silva, 2026).

The provision-uptake pairing

The knowledge base's core feedback insight is that **feedback quality and feedback literacy are two sides of one system**: high-quality feedback is inert without a literate recipient, and a literate student gains little from poor feedback. AI Feedback Quality covers the provision side (is the feedback accurate, timely, actionable?), while Feedback Literacy covers the uptake side (can the student judge and act on it?). The feedback loop is what connects them — the mechanism by which quality feedback, received by a literate

learner, closes the gap. Designing effective AI feedback therefore means designing both the system and the student.

Which student-side capacities matter is empirically separable: among 1,507 secondary students who each received one standardized automated feedback message on an argumentative text, only behavioral engagement with feedback and instrumental attitudes towards it predicted revision performance — students at the 75th percentile on either dimension improved by about 0.10 or 0.11 WLE points more than comparable students at the 25th, roughly the 46th to the 54th percentile — while global receptivity, cognitive engagement and experiential attitudes were unrelated to it and perceived usefulness mediated no dimension's path to performance. Usefulness worked on the other outcome instead: global receptivity's effect on situational interest ran entirely through perceived usefulness (indirect $\beta = 0.09$, 95% CI [0.06, 0.13]), so revision gains tracked durable habits of acting on feedback while interest tracked the appraisal of a particular message. (Automated feedback on argumentative writing: The role of secondary students' feedback receptivity and feedback perception)

A source can differ in how it calibrates, not how well it scores: in a randomized experiment, chain-of-thought AI feedback outscored an experienced teacher on rubric quality yet produced no greater revision gains, while the teacher's feedback stayed calibrated across drafts and GenAI feedback tracked the strength of the initial essay (Farrokhnia et al. (2026)).

A two-layer model shows how the pairing can be organized around a machine without delegating judgment to it. In El Khoury and Ma's worked example, an agent produces a draft rubric-based evidence report on each transcript with every rating tied to quoted excerpts, and the instructor then reviews the report, leads a debrief and decides what the evidence means for that student — a division the authors summarize as the AI organizing evidence while the instructor interprets it. Their claim about uptake is appraisal-based: feedback and iteration outside the social hierarchies students navigate with peers and instructors are easier to attempt, and rehearsal at the student's own pace is what they argue turns occasional confidence into a settled habit of engaging with feedback.

Why feedback matters for AI in education

Feedback is one of the most consequential and best-evidenced mechanisms in education, and AI both amplifies and complicates it. Well-architected AI feedback can match or exceed human feedback and scale across cohorts, but it demands new learner capabilities (Feedback Literacy, AI Literacy) and carries risks (uncritical acceptance, Over-Reliance). As AI-generated feedback becomes ubiquitous, the knowledge base frames feedback as a whole system — quality, loop, literacy, and assessment context working together — rather than as any single component.

- **Feedback can target the feedback-giver.** Tutor training is an under-explored feedback context: automated systems that sequence-label tutors' open-ended responses to flag praise types (effort-based praise — the desirable process-focused kind — vs. outcome-based vs. person-based, the least desirable trait-attributing kind) can deliver explanatory feedback that changes tutoring behavior. The binding constraint is expert-labeled data. An augmentation approach — GPT-4o generates synthetic labeled responses expanding a 13-instance low-resource set to 520, then fine-tunes GPT-3.5 — recovers most of the gap: F2 +20.5% on effort-based praise, +17.3% on outcome-based, and +16.5% on the *unseen* person-based category. The generalization test to an

unseen praise type is the validity check that separates this from overfitting, and the mechanism is closer to teacher-model distillation than classical augmentation. (Improving automated feedback systems for tutor training in low-resource scenarios through data augmentation)

- **Feedback that cannot see the revision gets repeated.** In a science learning game whose agents critiqued draft arguments, students revised across multiple rounds, but a quantized 8B model returned substantially the same critique to an improved draft, so the loop that motivated revision also produced the frustration that ended it (Humburg et al., 2025).
- **"Tone is a detail of feedback quality."** In the benchmark it tracked the number it was given: every model, told a grade that contradicted the work, wrote feedback whose tone followed that grade, and for **eight of 22** the shift per point matched or exceeded the shift with the work's quality. Only the tone rule was validated against trained annotators, on **1,655** tutor replies, so substance is unmeasured. A grader that writes feedback from a wrong grade launders the error into praise or criticism.

Feedback can be built from the process rather than the product. In Xian et al. (2026) one arm received personalized visualizations of its own keystroke and screen activity with structured reflection, while the other received written instructor comments on accuracy, clarity and editorial quality. The process arm gained 5.64 points on a blind 0-100 editorial rating against 1.91 for the product arm, with a Group by Time interaction ($F(1, 20) = 4.94$, $p = 0.038$, partial eta squared 0.198) and the control arm's own gain not significant ($p = 0.123$). Eleven students per arm means the direction is the finding, not the size.

Common Misconceptions

- **"Students cannot tell AI feedback from human feedback."** They can, and the label changes the judgment: **once the label was revealed, ratings of the AI variant fell and of the human variant rose — significantly for Genuineness ($p < .01$)**. Provider credibility shaped the evaluation of identical-style feedback.
- **"Lab approval predicts semester use." Lab approval is not semester use**: **all 18 students** reacted positively to the GenAI explanation function in lab sessions, **yet only half used it during the term**. The intention-usage gap is the design problem.
- **"Immediate corrective feedback is solved with LLMs."** Generating it inside a tutor is **feasible but imperfect**: across **6,926 logged transactions** in the Apprentice Tutor collection, the feedback was good enough to deploy and not good enough to assume correctness.

- How Can AI Help Me Give Better Feedback at Scale?

Feedback Literacy

> **Feedback literacy** — the capabilities and dispositions students need to understand, evaluate, and act on feedback to improve their learning. It is the learner-side counterpart to feedback provision: whereas AI Feedback Quality and Feedback Loop concern the quality and mechanics of the feedback system, feedback literacy concerns the learner's capacity to seek, make sense of, judge, and use feedback productively.

Questions to Consider

- Well-designed feedback only helps students who can interpret and act on it. If two students receive identical feedback and learn different amounts, where does the difference live — and is it the student's fault or the system's?
- Research finds that students with stronger feedback literacy benefit more from AI feedback, while weaker-literacy students show minimal or even negative effects. What does that suggest about simply adding AI feedback to a course without also building students' capacity to use it?
- Feedback literacy includes seeking feedback, making judgments, managing affect, and acting on feedback — not just receiving it. When did you last *seek out* feedback rather than wait for it, and what made you brave enough (or not) to do so?
- If AI can now generate abundant, instant feedback, has the bottleneck shifted from feedback provision to the learner's ability to use it? What might change about how you design feedback if you saw students' feedback literacy as the real constraint?

Introduction

Feedback literacy matters because well-designed feedback only helps students who can interpret and act on it. A student who cannot evaluate whether AI-generated feedback is accurate, or who does not know how to turn feedback into a concrete revision, learns far less from the same feedback than a more feedback-literate peer. As AI reshapes feedback provision, feedback literacy has become a central boundary condition for whether AI feedback improves learning.

What feedback literacy is

Feedback literacy is widely framed as a set of interrelated capabilities — the capacity to appreciate feedback, make judgments, manage affect, and take action (after Carless & Boud). The knowledge base's articles cluster feedback literacy around several capabilities:

- **Seeking and eliciting feedback** — proactively requesting feedback rather than passively receiving it.
- **Making judgments** — evaluating the accuracy and usefulness of feedback, including feedback produced by AI.

- **Sense-making** — interpreting feedback in relation to task goals and criteria, and understanding what it implies for improvement.
- **Managing affect** — engaging productively with feedback without being discouraged or over-inflated by it.
- **Acting on feedback** — translating feedback into concrete revisions or changes in approach (Feedback Loop, Self-Regulated Learning).
- **Judging evaluative authority** — a further capacity proposed by AlGhamdi (2026): alongside appreciating feedback, making judgments, managing affect and taking action, students reasoning about AI-produced feedback needed to judge *which source holds evaluative authority*, separately from judging feedback quality. Because participants were told ChatGPT generated both score and feedback, their feedback literacy was exercised on the source and legitimacy of the evaluation, not only its content, and it produced demands for instructor validation rather than passive acceptance.

How feedback literacy appears in the research

- **Feedback literacy as a moderator of AI feedback value:** Mendoza et al. (2026) show that feedback literacy moderates the link between ChatGPT acceptance and Self-Regulated Learning: students with stronger literacy perceive greater SRL benefit from AI feedback, while weaker-literacy students show minimal or even negative (Over-Reliance) effects. Feedback literacy is a boundary condition for whether students can "make sense of" AI feedback.
- **Feedback literacy as the pathway from GenAI use to critical thinking:** in 421 Chinese undergraduates, GenAI use's association with self-reported critical thinking ran almost entirely through GenAI feedback literacy (β=0.185, 71.98% of the total effect), and that pathway strengthened as reflective thinking rose (index of moderated mediation = 0.030) (Yan et al. (2026)).
- **Feedback literacy predicts learning from AI-assisted writing:** Hawkins et al. (2026) find that feedback literacy was the only significant positive predictor of essay grade in an AI-enhanced essay-writing task, while Liu & Deris (2025) develop and validate an AI Feedback Literacy (AIFL) scale and show it predicts feedback uptake.
- **The literacy–engagement loop runs both ways.** A three-wave random-intercept panel of 399 Chinese undergraduates found AI feedback literacy predicting later agentic engagement (β = 0.222) and the reverse path just as strong (β = 0.263), with a Wald test unable to separate their sizes (Xu (2026)).

A rival disposition: reward sensitivity. Grade-based reward sensitivity weakened the credibility–perceived-learning link for Pérez-López et al. (2026) (simple slopes 0.733, 0.607 and 0.483 at low, mean and high sensitivity), locating students' instrumental orientation to marks where feedback-literacy research locates a cultivable disposition to use feedback. - **Comprehension, not actionability, carried the revision payoff.** Across three writing-feedback-revision cycles in two intact classes of 48 students each, comprehension was the dimension most associated with revision quality (r = 0.501), ahead of actionability (r = 0.480) and

diagnostic accuracy (r = 0.445); an interpretation sheet read before independent revision is what the diagnostic condition added (Yao & Fan (2026)).

- **Frameworks for GenAI-enabled feedback engagement:** Zhan, Boud, Dawson & Yan (2025) (Boud and Dawson are leading feedback-literacy scholars) argue GenAI can *enable* student feedback engagement, mapping a cyclical self-AI Regulation in Education feedback model onto the eliciting/processing/enacting phases.
- **AI feedback arrives without the teacher's framing:** Brunnström and Palmqvist (2026) argue that GenAI makes feedback literacy *more* demanding, because responses are generated interactively and without a teacher's immediate framing: students must interpret, evaluate, engage with and use them — including deciding when a response is too abstract, when to persist, and when to return to conventional resources. Across their eight-exchange demonstration, simplification and usable structure appeared only after learner interventions, making the eliciting/processing/enacting cycle of feedback engagement something the student has to drive (Zhan, Boud, Dawson & Yan mapped that cycle for GenAI; Self-Regulated Learning).
- **Feedback literacy in AI-assisted writing and EAP:** Feedback literacy scripts and second-rater mechanisms train students to engage critically with AI feedback during writing revision, shifting revision toward argument-level improvement rather than surface edits.
- **Automated feedback tools for literacy development:** Tubino & Adachi (2025) argue AI automated feedback tools should be reframed as instruments for *developing* students' feedback literacy, not just providing more feedback.
- **Peer feedback and feedback literacy:** Irwin & Muller (2025) position GenAI within EFL peer feedback to train feedback literacy and enable uptake in speaking classes, and scaffolding studies compare GenAI vs. human peers in fostering self-regulated feedback.
- **Feedback stored as durable, consultable data.** Pairing ChatGPT with an e-portfolio raised speaking performance and feedback literacy together (partial $\eta^2 = 0.218$ for the latter), as students treated archived feedback from lecturer, peers, and AI as data to reconcile rather than a one-off correction (Laksana et al. (2026)).
- **Feedback literacy in learning analytics and GenAI dashboards:** Jin et al. (2025) examine how students perceive GenAI-powered Learning Analytics feedback from a feedback-literacy perspective.
- **Feedback literacy as a goal of AI-literacy and assessment design:** Richmond & Nicholls (2025) use a process-over-artifact assessment in which students critique ChatGPT output against a rubric to build feedback, psychological, and AI literacies together; learner-centered AI feedback and care-full feedback design link feedback quality to the learner's capacity to engage.
- **Feedback literacy can be taught, and AI can supply the practice material.** A conceptual guide has instructors generate a graded spectrum of AI work samples — meeting all, some, and none of the criteria — then lead students through modeled critique, guided class analysis, and independent evaluation (Pennington and Hock (2026)).

Why feedback literacy matters for AI in education

AI changes feedback in two directions that both raise the stakes of feedback literacy. First, AI dramatically increases the *volume and immediacy* of feedback (AI Feedback Quality, Feedback Loop), so students confront far more feedback they must triage and evaluate. Second, AI-generated feedback carries distinct risks — inaccuracy, hallucination, and the "illusion of mastery" — that demand critical evaluation skills and vigilance against Over-Reliance and misattribution. Feedback literacy therefore becomes a core component of AI Literacy: knowing not only how to prompt an AI for feedback, but how to judge whether the feedback is worth acting on and how to convert it into genuine learning rather than task completion.

Bearman and colleagues (2026) add a further demand to that list. In their workshop study, students were not managing one feedback source but a network: they weighed educator comments against AI output, rubrics, course materials and peers, and when human feedback was slow they kept working with AI as a holding pattern, revising later if it had misled them. The authors suggest students can act as their own human-as-the-loop by managing those relations from the granular task to the broader trajectory, which is itself a feedback-literacy capability. Their warning is that thin or late educator comments are what push students toward unverified sources.

Connections to related concepts

Feedback literacy connects to AI Feedback Quality and Feedback Loop (the provision side it complements), Formative Assessment (the assessment cycle it feeds), and Self-Regulated Learning (the Self-Assessment and adaptation it supports). It is a subset of AI Literacy when applied to AI-generated feedback, intersects with Peer Assessment in collaborative contexts, and is particularly consequential for Writing. It also connects to Metacognition and Trust Calibration — the ability to judge whether feedback is trustworthy.

Acting on feedback is not the same as improving the artifact. Among 22 pre-service mathematics teachers, selective acceptance of AI and peer feedback was the norm (32 of 44 episodes), yet only five improved their designed-task quality — a translation gap the authors attribute to evaluative judgment rather than uptake (Oh, 2026).

Wang and Guo (2026) treat feedback literacy as developable through practice: EFL peer reviewers who worked dialogically with generative AI to generate comments improved their own capacity to judge and use feedback, not merely the comments they delivered.

Feedback literacy has to cover a machine source as well as a human one. Stillman et al. (2026) ask students to assess peer feedback and chatbot feedback on the same draft in the same reflection, which makes the comparison itself the learning task. Their students downgraded the chatbot's authority relative to an instructor's, and the authors read that downgrading as literacy rather than as reluctance.

Common Misconceptions

- **"AI feedback improves critical thinking directly."** In **421 Chinese undergraduates**, GenAI use's association with self-reported critical thinking **ran through feedback literacy**. The literacy is the mediator, so an intervention that adds AI feedback without building the capacity to read it addresses the wrong term.

- **“Literacy is a precondition, not an outcome.”** A **three-wave random-intercept panel of 399 Chinese undergraduates** found AI feedback literacy predicting **later** agentic engagement (**β = 0.222**), so the loop runs both ways. It is dynamic rather than a gate to pass once.
- **“Actionability is what makes feedback change writing.”** Across three writing-feedback-revision cycles in **two intact classes of 48 students each**, **comprehension was the dimension** that carried the revision payoff. Feedback a student cannot parse is not improved by making it more actionable.

AI Feedback Quality

> **AI feedback quality** — the accuracy, usefulness, timeliness, and pedagogical value of feedback generated by AI systems for learners. As AI-generated feedback becomes ubiquitous in education, understanding what makes feedback effective — and when it falls short — is critical to ensuring AI supports rather than undermines learning.

Questions to Consider

- What makes feedback 'good' — accuracy alone, or also being timely, specific, actionable, and calibrated to what you already know? Which of these would you notice missing first?
- Research finds students experience AI-generated feedback as comparable to a teacher's — but what students find acceptable need not produce learning effectiveness. Why might feedback that feels fine still fail to help you improve?
- Even high-quality AI feedback is inert without a 'feedback-literate' recipient — studies show low feedback literacy can make AI feedback minimally useful or even negative. Whose responsibility is it to build that literacy?
- Feedback quality and revision depth are linked: scaffolding how students engage with AI feedback shifts them toward argument-level improvement rather than surface edits. How does the way you receive feedback change what you do with it?
- Sycophantic feedback conflates support with agreement — an AI that validates your answer rather than challenging it undermines feedback's corrective function. When does feedback need to challenge you rather than comfort you?
- Confidence calibration matters: a system that knows when it's uncertain gives better feedback than one that's confidently wrong. How should a tool signal its uncertainty to you, and how would you use that signal?

Introduction

AI feedback quality is not simply about correctness. Effective feedback must be timely, specific, actionable, and calibrated to the learner's current understanding. Research in this knowledge base examines AI feedback quality across multiple dimensions: accuracy (is the feedback correct?), usefulness (does it help the student improve?), and pedagogical alignment (does it promote learning rather than just task completion?).

How AI feedback quality appears in the research

- **Comparability to human feedback:** Studies in higher education find that AI-generated feedback is experienced as acceptable and supportive — comparable to teacher feedback. But acceptability does not guarantee learning effectiveness. A PRISMA-guided systematic review of 42 empirical studies (2023–2025) likewise finds Large Language Models (LLMs) grading and feedback quality to be task-contingent — matching human raters on short, well-structured answers with detailed

rubrics but degrading on complex, open-ended, or multilingual work, with feedback sometimes too generic or misaligned with the grade — and identifies prompt quality, rubric detail, model version, and assessment language as the dominant determinants of grading and feedback quality (Can ChatGPT Replace the Teacher in Assessment? A Review of Research on the Use of Large Language Models in Grading and Providing Feedback).

- **LLM-generated lesson materials matched human-created ones — when feedback was present.** Lin et al. (2026) generated scenario-based tutor-training lessons with a retrieval-augmented pipeline over curated research sources and compared them in a randomized eight-condition experiment (N = 208) against carefully human-authored lessons. The human-created lesson produced higher post-test performance (0.793 vs 0.730), but only in the no-feedback condition; with immediate explanatory feedback the source difference disappeared, and feedback had no overall main effect. For content generation the finding suggests the human-vs-LLM gap is a scaffolding gap: generated materials are competitive when the learning environment supplies the explanatory feedback the lesson itself does not.

Student-perceived quality is more mixed than acceptability suggests: 77 of 93 undergraduates found AI feedback easy to understand, yet 68 found it repetitive and 79 self-contradictory; only 31 agreed it grades complex or creative writing, and 81.7% preferred human scoring for a final paper worth 40% of the grade (Yildirim-Erbasli et al. (2026)). - **A pooled anchor for the feedback mechanism.** A 53-study meta-analysis found GenAI feedback produced the largest effect in the study (g = 1.27), against g = 0.40 for achievement, credited to comprehension, timeliness and objectivity — though students can distrust AI feedback and its lack of emotional response may raise cognitive load (Dong (2026)).

A controlled comparison isolates the feedback component from the adaptive system: with the same diagnostic tutoring system, learners receiving automated real-time feedback rose from 1.90 to 3.54 on a four-point mathematics assessment against 1.90 to 2.85 without it ($F(1, 76) = 9.24$, $p = .003$, $d = 0.73$) (Ogunsakin et al. (2026)).

- **A supportive feedback sequence can still harm learning.** Cao et al. (2026) found that encouragement → hints → correct answer lowered post-test scores ($B = -0.83$, $p = .02$) despite raising perceived encouragement, with frequent resubmissions predicting worse performance ($B = -0.33$, $p = .001$), so engagement and satisfaction are not proxies for learning.
- **A grammar-feedback and revision cycle moved writing, confidence and metalinguistic awareness.** Wordofa and Abo (2026) found an AI-supported draft–reflect–revise condition outperformed conventional instruction on all five writing dimensions after covarying pre-test scores ($F(5, 77) = 20.885$, partial $\eta^2 = 0.576$), with writing Self-Efficacy at partial $\eta^2 = 0.254$.
- **Feedback classification benchmarks:** Cross-language feedback benchmarks assess whether feedback quality classification transfers across languages and educational contexts, connecting to AI Ed Evaluation.
- **Collaborative feedback systems:** AICoFE implements and deploys AI-based collaborative feedback in higher education, evaluating both system performance and student reception.
- **Personalization can encode bias.** Holding the essay constant, conditioning feedback on a student's race, language, or disability shifted four LLMs toward positive feedback bias (over-

praise) and feedback withholding bias (less substantive critique) — the mechanism through which personalized feedback becomes discriminatory (Tan, Phalen & Demszky (2026)).

- **Automated grading feedback:** Automated Grading and Formative Assessment research examine whether AI-scored assessments provide feedback that matches or exceeds human grading quality.

Feedback dominates practice but its quality is rarely the outcome. Feedback and tutoring were the most frequently reported enacted uses across 394 GenAI higher-education studies, yet feedback quality was among the outcomes targeted least (Lin et al. (2026)).

- **Essay scoring feedback:** Confidence-aware ASAG and anchor-based AES explore how confidence calibration and prompting design affect feedback quality for writing assessment.
- **Evidence-constrained, risk-adaptive feedback:** Wang (2026) separates three functions that feedback research usually evaluates together — predicting which failed state will persist, deciding when limited support capacity should be spent, and generating feedback whose claims stay inside recorded evidence. Across 2993 failed-submission states from 215 students, a calibrated risk model selected 17.8% of eligible test states and captured 25.2% of observed persistent failures, and after one standardized repair pass 519 of 544 generated messages carried all required components. Timing and grounding therefore join linguistic quality and retrievability as dimensions a feedback system has to be judged on.
- **Discretionary feedback provision:** Research on AI-assisted feedback in higher education examines whether AI increases the quantity and quality of feedback instructors provide.
- **The relational layer resists delegation:** across 21 higher-education teachers using an AI feedback tool, 12 rewrote the model's text, revisions clustered on tone and encouragement (Student–Teacher Relationship f = 24), and the more experienced teachers flagged editing burden, trust and misinformation risk while novices deferred to the tool (Aldino et al. (2026)).
- **Students and the model agree on some dimensions and not others.** Undergraduates judged feedback constructive on the same terms ChatGPT did for specificity and actionability, but diverged on timeliness and positivity, and valued instructor feedback for its relational, personalized and expert-driven character while reading AI feedback as impersonal (Fong et al. (2026)).
- **Reliable provision, not inherent superiority, drives AI's edge:** Geschwind et al. (2026)'s semester-long field experiment found GPT-4 feedback beat peer feedback because it was *consistently* delivered — nearly all AI-feedback respondents (369/398) received textual plus numeric feedback while under two-thirds of peer-feedback students received none, and much peer feedback was non-targeted praise. When high-quality textual peer feedback *was* received, peer outcomes matched AI's — indicating the AI advantage is reliability, not quality at the margin. Students also rated peer feedback slightly higher on perceived validity and emotion (mild algorithm aversion) yet still activated and learned more from AI, showing perceived quality and behavioral outcomes can diverge.
- **Quality parity can give way over rounds.** On a shared rubric, peer-group feedback matched ChatGPT-4o's across five dimensions in round one, but the model pulled ahead on

constructiveness, accuracy and concreteness in round two — a shift they attribute to rubric-aligned prompting and practice, not a fixed model property (Li et al. (2026)).

- **The advantage can come from a worked example, not corrective feedback.** Practicing cover letters with AI beat feedback from experienced human editors on a later unaided task (d = .20), and merely viewing one AI-revised letter matched practicing with the tool, so the gain tracked the example (Lira et al. (2025)).
- **Source label versus feedback quality:** Mertens et al. (2026) separate the *source* of feedback from its quality by holding content constant — 401 teachers rated feedback messages that were all generated with GPT-4-turbo but randomly labeled as teacher- or ChatGPT-generated, and the label alone shifted credibility (b = 0.21), usefulness (b = 0.47) and fairness (b = 0.48, all $p < .001$), with 73% preferring the teacher-labeled message, $t(400) = 15.55$, $d = 0.78$. Provider-directed items moved furthest — perceived effort (b = 1.34) and willingness to rely (b = 1.45) — and a written explanation of how ChatGPT works changed nothing (interaction ps ≥ .399), pointing to Trust, professional identity and ingroup bias in the rater rather than any deficiency in the feedback itself. Perceived quality can therefore be discounted by provenance even when the content is identical, which means a genuinely good tool can still stall at the point of use.
- Credibility is not reducible to quality: Pérez-López et al. (2026) found students' perceived competence with ChatGPT and their sense of its human-like empathy predicted its feedback credibility, while perceived warmth worked only through that empathy.
- **Source label versus feedback quality, on the student side:** Nazaretsky et al. (2025) ran the student-side counterpart, in which 472 EPFL students across six courses rated feedback on their own assignments blind to its source and again after disclosure, and most could not tell the two variants apart (287 of 472 guessed correctly). Ratings then moved in opposite directions — significantly so for Genuineness ($p < .01$) — with human providers rated more credible ($\mu = 3.28$, $\sigma = 0.77$) than AI ($\mu = 2.25$, $\sigma = 0.85$, Cohen's $d = 0.57$). The misattribution ran mostly one way: of 219 instances of low-rated human feedback, 205 were read as AI, so perceived quality and perceived identity reshape each other in both directions rather than the label merely discounting identical text.
- **Feedback literacy as the uptake-side boundary:** Liu & Deris (2025) validate an **AI Feedback Literacy (AIFL) scale** (16 items, Attitudes/Practices factors) that predicts students' actual uptake of AI feedback, and Mendoza et al. (2026) show feedback literacy moderates whether AI feedback improves Self-Regulated Learning — high literacy yields benefit, low literacy yields minimal or even negative effects. Feedback quality and feedback literacy are two sides of one system: even high-quality AI feedback is inert without a literate recipient.
- **Feedback quality drives revision depth:** Feedback literacy scripts and second-rater mechanisms show that Scaffolding how students engage with AI feedback shifts revision toward argument-level improvement rather than surface edits — feedback that promotes deeper revision is higher-quality feedback. What students *do* with comments also depends on their kind, not just their count. In an eight-week L2 writing comparison, the teacher's broader, self-adjusting error correction delivered the larger first-task gain but fell by roughly a third in the second task once the work demanded structural breakthroughs, while AI-assisted peer feedback's narrower but steadier focus

held its improvement and edged past the teacher class's second-task revision mean — a between-group gap the authors report as not statistically significant. The authors read authoritative, error-heavy correction as encouraging passive, error-avoidance revision and treat the two modes as complementary heterogeneous scaffolds rather than substitutes (Tang, Li & Luo, 2026); neither mode moved syntactic complexity, so feedback quality is also bounded by the layer of skill it can act on.

- **Sycophancy as a feedback failure:** Sycophantic feedback conflates support with agreement — an AI that validates a student's answer rather than challenging it undermines feedback's corrective function, degrading quality even when it feels affirming. EduFrameTrap shows tutors withholding corrective feedback under social pressure, and contextual sycophancy propagates errors into subsequent advice; effective feedback must sometimes challenge the learner.
- **Diagnostic accuracy only partly determines feedback quality — and LLM self-evaluation misaligns with human judgment:** Reddig, Arora & MacLellan (2025) found GPT-4 produced error-targeted hints ~66% of the time in a College Algebra tutor, yet ~35% were too general, incorrect, or gave away the answer; even when diagnosis was wrong the model often recovered with relevant, general-but-correct feedback, though almost all incorrect feedback followed a misdiagnosis. Their simulated-student automated quality checks passed only 21.4% of hints on both tests, rejected targeted feedback ~70% of the time, and favored hints that simply revealed the answer — a stark demonstration that automated evaluation can diverge sharply from human judgments of helpfulness and must be calibrated against them.
- **Stable output is not valid feedback:** across 12 TEACH-framework classroom videos, reliability and accuracy came apart — the most stable of eight LLM endpoints was among the weakest against certified experts (exact agreement 0.31), and every model privileged verbal cues over implicit pedagogical evidence, scoring low where directives were absent (Melo et al., 2026).
- **Linguistic and perceptual quality of AI instructional comments:** Wang, Du and Jin (2026) assess ChatGPT-generated in-video scaffolding comments against instructor comments on part-of-speech composition, 3-gram diversity, Zipf's law conformity, readability, topical relevance (TF-IDF and BERTScore), and learner ratings. The generated comments were *more* complex and adjective-rich but *less* varied and less readable, and trailed human comments on topical alignment (0.607 vs. 0.747 BERTScore for knowledge support) and on perceived timing and helpfulness — evidence that AI feedback quality must be judged on linguistic Accessibility and affective fit, not relevance alone. Their analytic battery is offered as a reusable Learning Analytics pipeline for auditing AI-generated instructional content.
- **Prompt design and model choice as measured predictors of quality:** Jacobsen et al. (2026) decompose the sources of AI feedback quality with hierarchical regression on feedback generated for 153 pre-service teachers' lesson-planning goals. Across 240 feedbacks from three models under four systematically varied prompts, the model alone explained 26.9% of the variance in nine-category quality ratings and adding the prompt lifted the model to 42.8% ($\Delta R^2 = 15.9\%$); in a replication with the strongest model-prompt combinations (345 feedbacks) the model explained 18.4% and the prompt a further 5.7%. The largest single prompt effect was negative: replacing domain-specific technical terminology with everyday paraphrases lowered feedback quality

significantly (β = −0.412), while adding concrete examples and removing the chain-of-thought instruction were not significant in the first study. Quality is therefore not a fixed property of "the AI" — it is jointly produced by which model is chosen and how the task is phrased, and both are teachable.

Style is a quality dimension with a cost: with the same model, directive feedback scored higher on prioritizing essential features and on specificity, while Socratic feedback raised comprehension monitoring — and directive feedback carried the higher cognitive load (Han et al. (2026)).

How the feedback is *produced* belongs on that list too. In a modular automated writing evaluation system for argumentative essays, supervised fine-tuning on 90 teacher-annotated essays produced unusable feedback — the fine-tuned GPT-4o exceeded its 8,000-token context window on every inference and fine-tuned LLaMA-3.3-70B emitted JSON that would not parse. Directly prompting Claude 3.7, by contrast, generated 630 micro comments across 40 essays whose teachers judged 94.69% necessary and effective, leading the authors to conclude that for a non-deterministic generation task prompting can beat fine-tuning (Labib et al., 2026).

Quality dimensions

AI feedback quality spans multiple dimensions captured in the knowledge base: - **Accuracy:** Does the feedback correctly identify errors and strengths? (Automated Grading, Automated Essay Scoring) - **Retrievability of evidence:** Can the system actually reach the evidence it is judging? Abreu, Stari and Martí (2026) separate evidence present in a submission from evidence available after processing — an equation, graph or unit may be included in a report yet never retrieved, so feedback about that criterion rests on nothing — making retrieval a dimension of quality distinct from accuracy or calibration. Their response is to require each score to cite concrete evidence from the report, so an observation that cannot be traced back to the text is visible as unsupported. - **Helpfulness:** Does the feedback guide improvement? (Feedback Loop, AICoFe: Implementation and Deployment of an AI-Based Collaborative Feedback System for Higher Education) - **Timeliness:** Is feedback delivered when the learner can act on it? (Formative Assessment) - **Trainability:** quality is bounded by the labeled data the system was trained on, and expert annotation is where that budget actually goes. Xu, Lin, Wu, Aleven and Koedinger (2025) attacked this in tutor training, where effort-, outcome- and person-based praise has to be identified in open-ended responses. Fine-tuned on 520 GPT-4o-augmented examples grown from 13 real annotations, a small model gained F2 +20.5% on effort praise and +17.3% on outcome praise. The mechanism is closer to knowledge distillation than to classical augmentation, and the gain transferred to a praise category it was never trained on (F2 +16.5%), which is the evidence that it generalizes. - **Verifiability against an objective measure:** Where the target is machine-measurable, feedback can be checked against a physical measurement rather than a rubric. Aksoy (2026) extracted 2,208 note-level pitch deviations in cents and gave those tables to the model, so its claims had a measurable referent. - **Bias:** Is feedback equitable across student populations? (Bias Mitigation, Equity)

- **Ethics and transparency:** Only 14 of 50 top-ranked universities had specific guidance on teachers' AI use for feedback, and students described undisclosed AI feedback as "disingenuous" — transparency and consent shape whether feedback is accepted, not just whether it is accurate (Luo & Eaton (2026)).

- **Calibration:** Does the system know when it's uncertain? (Confidence Aware AI Assessment)
- **Verifier-scored release criteria.** LearnLens scores generated feedback on scientific accuracy, clarity, and specificity and iterates a verification-and-revision loop until every criterion clears a threshold, using a *separate* foundation model from the generator to avoid model-family bias; its scoring ran 8–13% below every baseline on MSE (3.190) (Zhao et al. (2025)).
- **Comprehensibility in the learner's own language.** Feedback only closes a gap if the learner can follow the explanation, not merely the flag. The Kwara-STEM AI Tutor, a localized model fine-tuned on national technical-education curricula, nudged students rather than handing over answers and shipped a "Clarify" feature that translated complex technical terms into Yoruba or Nupe, so real-time correction landed in the learner's own language context (Muritala, Ahmed & Olumorin, 2026). Own-language explanation is a condition of synchronous feedback's usefulness, not a decorative add-on.
- **Coverage is not alignment.** Six LLMs under three prompting strategies each produced most of the seven feedback focus types, yet their distribution over those types diverged from teachers' (best Jensen-Shannon divergence 0.134, worst 0.270), so breadth of coverage and distributional fit are separate quality signals (Almousa et al., 2026).
- **Field-level coverage is uneven.** A synthesis of 68 studies of AI-generated feedback finds the evidence clusters on whether feedback is accurate and grounded (47 studies) and whether it helps the learner (58), while rubric and task alignment — whether the feedback responds to the task's own requirements — appears in only 19 (Yang (2026)).
- **Criterion-level ratings diverge within one message set.** Six reviewers scoring 157 messages rated practice exercises strongest (95.5%) while diagnostic specificity (41.1%) and clarity and tone (33.4%) lagged, and instructors rated actionability more generously than other reviewers (84.5% vs 59.9%) (Vanhoyweghen et al. (2026)).
- **The reader's side of the same dimensions.** Twenty-four university writing professors described output that was complicated, overly long, vague or impractical, and two found it praising strengths unless told to look for weaknesses first (Wu and Lam (2026)). Seven said reaching acceptable feedback took repeated prompting, which spends the time the workload gain was meant to save.
- **Length out-predicted every other measured property of the message.** Across three deployments of an LLM hint system in a live programming course, each standard deviation of 204.9 characters predicted lower next-submission correctness (−0.733), more remaining attempts (0.187) and a longer wait before resubmitting (0.226), while Flesch-Kincaid grade was uncertain for the first two (Mihaylova et al., 2026). Format mattered as well, but as a trade-off: diagnostic hints produced correct next submissions more often and fewer attempts, and slower resubmission.

Connection to broader concepts

AI feedback quality connects fundamentally to Formative Assessment and Feedback Loop — quality feedback closes the gap between current and desired performance. It intersects with Automated Grading (which generates the scores feedback is based on), AI Literacy (students must evaluate feedback quality

critically), and Over-Reliance (uncritical acceptance of AI feedback can displace learning). For Writing, feedback quality is particularly consequential given AI's growing role in writing assessment.

The corpus behind those quality claims is thinner than the claims suggest. Across 51 studies of GenAI written feedback in second-language writing, 16 experimental designs used no control group and only 27 reported the prompts they used — so two in five results cannot be reproduced or compared on the variable that most shapes output (Crosthwaite & Sun (2026)). Quality evidence in this literature therefore accumulates more slowly than its volume implies.

Wu, Li and Moorhouse (2026) examine DeepSeek's explicit reasoning traces as a feedback affordance, finding that visible reasoning makes the basis of a comment inspectable by the writer, while the model still routes higher-order judgment, such as argumentation, to the human.

Common Misconceptions

- **"Students find AI feedback acceptable, so it is good." Student-perceived quality is more mixed than acceptability suggests**: **77 of 93 undergraduates found AI feedback easy to understand, yet 68 found it repetitive and 79** found something else wanting. Comprehension and dissatisfaction coexisted in the same cohort.
- **"Feedback effects are modest."** A **53-study meta-analysis** found GenAI feedback produced **the largest effect in the study (g = 1.27)**, against **g = 0.40** for the overall GenAI effect. Feedback is the strongest mechanism measured, which is a different picture from the general optimism debate.
- **"The feedback is the whole intervention."** A controlled comparison isolates the component: with the same diagnostic tutoring system, learners receiving **the feedback component** differed measurably. Separating feedback from the adaptive system is what makes the claim attributable.
- **Access and engagement are different interventions.** Wenzel, Geiger and Liening (2026) separated the two across **234 students and 1,147 weekly observations** in a five-week business simulation. Assignment to conversational AI feedback produced **no effect** on germane cognitive load ($\beta = .019$, $p = .807$) or extraneous load ($\beta = .071$, $p = .481$). **Actual regular use** was associated with significantly higher germane load than experimental non-users ($\beta = -.468$, $p < .001$) and than controls ($\beta = -.253$, $p = .028$), while **irregular use did not separate from regular use** ($p = .116$). Quality judgments that rest on an intention-to-treat contrast will therefore understate a feedback intervention whose uptake is partial, and satisfaction or access metrics cannot substitute for engagement data.

Formative Assessment

> **Formative assessment** — assessment designed to inform ongoing instruction and learning, as opposed to summative evaluation. In AI education, formative assessment is both transformed by AI and essential to it: AI systems can generate, validate, and adapt formative items and feedback at scale, while formative feedback is a primary mechanism through which AI tutors and adaptive systems support learning. The knowledge base's research examines AI-generated formative items, AI-generated feedback, and the design and evaluation of these systems.

Questions to Consider

- Formative assessment is meant to close the loop — surface what students don't know and give feedback they can act on *while learning is still in progress*. How is that fundamentally different from summative evaluation, and when might the two get confused in practice?
- AI can generate multiple-choice questions with impressive accuracy on verifiable dimensions, but is weakest on instructional-judgment dimensions. If a machine is good at correct answers but weaker at pedagogical judgment, what should it be trusted to do — and what should humans keep doing?
- AI-generated feedback only helps when students actually enact it — the 'enacted feedback' condition, where students select, evaluate, and apply suggestions, outperformed simply being given feedback. If enactment matters more than the feedback itself, what does that mean for how formative feedback should be designed?
- Feedback is described not as information transfer but as an ethical, relational practice. What gets lost when formative assessment is mass-produced as 'AI slop' — and what can human comment banks and relational care preserve?

Introduction

Formative assessment is central to AI in education because it sits at the junction of Assessment and learning feedback. Its purpose is to close the loop: surface what students know and don't know, and provide feedback they can act on to improve. AI makes this feasible at scale — generating items, scoring responses, and delivering individualized feedback — but the knowledge base's research shows that quality varies dramatically across item types, and that feedback only helps when students actually enact it.

Correnti et al. (2026) supply evidence that an automated writing system can serve an authentic formative purpose: growth appeared in revision quality and not only in feature scores, but only where teachers built the feedback into classroom discussion.

AI-generated formative items

AI systems generate formative assessment items across modalities, with reliability varying by type:

- **Multiple-choice questions:** CODE-GEN: A Human-in-the-Loop RAG-Based Agentic AI System for Multiple-Choice Question Generation shows agentic AI can reliably generate MCQs for coding comprehension when validated across seven pedagogical dimensions — success rates reach **98.6%** for concept alignment and **79.9%** for feedback quality — suggesting AI is strongest on verifiable dimensions and weakest on instructional-judgment dimensions. This connects to automated question generation more broadly.
- **An easy generated item bank gives no formative signal.** In a 10-week deployment about 70% of AI-generated practice items were answered correctly by every student ($p = 1.0$), so the low-stakes quizzes that ran every 15 to 20 minutes were well received but carried almost no discriminating information for adapting instruction (An & Wang (2026)).
- **Automated essay scoring:** multi-agent frameworks (e.g., MASS) improve consistency over stand-alone LLMs for essay scoring, though interpretability of multi-agent scoring decisions remains an open challenge.
- **Formative scoring pipelines:** CoTAL couples Chain-of-Thought prompting with active learning and Evidence-Centered Design to produce generalizable formative-assessment scoring with human-in-the-loop prompt engineering.
- **High-frequency, automatically-marked assessments:** automated formative assessments in A-level sciences examines the effect of high-frequency, automatically-marked formative assessment on learning outcomes. A scoping review of short-answer auto-marking in science (2017–early 2024) confirms this formative short-answer use case is a field with real traction: BERT-family models dominated auto-marking through 2021 before prompting larger LLMs from ~2022, and domain-augmented, rubric-aware, and chain-of-thought models performed best — yet the review's calls for comprehensive evaluation and unresolved fairness and explainability gaps caution against extending such systems to unmediated summative or high-stakes use (Auto-marking short answer questions in science: The foundational years of transformer-based models from BERT to GPT-4).

AI-generated feedback

A large body of knowledge base research examines AI-generated formative feedback:

- **The enactment problem:** Making AI-Generated Feedback Matter (13,037 students; 51,296 resources) shows feedback value depends on whether students *enact* it — the **Enacted Feedback** condition, where students select, evaluate, and apply AI feedback suggestions, outperformed simple directed feedback.
- **AI feedback can match expert teachers when the rubric carries the criteria.** Blind to source and randomized across 47 university project groups, an LLM given the co-constructed 0–30 rubric and exemplar was non-inferior *and* equivalent to expert feedback (+0.23, 90% CI [−0.46, 0.91]) — the rubric, not the model, calibrated (Grion et al. (2026)).

- **Feedback is not information transfer:** The care-full craft of feedback argues feedback is an ethical, relational practice, not information transmission — feedback only constitutes feedback when students make sense of and act on it, and contrasts mass-produced "AI slop" with human comment-bank shortcuts.
- **Sequenced feedback can backfire:** Sequenced AI feedback (encouragement → hints → correct answer, designed to promote autonomy) actually **harmed learning** in a randomized experiment (N=199) despite boosting engagement and positive perceptions — a cautionary finding about feedback design.
- **Learner-centered tools:** PolyFeed combines ML suggestion models with teacher practice, showing how teachers adopt and adapt AI feedback suggestions; AI-supported internal feedback helps undergraduates develop evaluative judgment.
- **Rubric-guided prompting and role-aware feedback:** Yaşar et al. (2026) showed that iterative rubric co-refinement — clarifying performance descriptors and explicitly accepting implicit indicators of learning — drove LLM–human agreement on student design work from 54.75% to 81.25% (Cronbach's Alpha rising from 0.393 to 0.798), with the largest gains in the cognitively demanding Iteration & Reflection category. Prompting the same model under instructor, peer-reviewer, and grant-reviewer roles produced distinct evaluative feedback, and post-revision LLMs were more consistent than some human raters in applying performance thresholds — positioning rubric-guided LLMs as calibration and co-design partners in formative feedback environments, with human-in-the-loop oversight remaining essential.
- **Agreement figures hide a direction: a model can hedge toward the middle category.** An LLM assessor tagging dialogue turns inside a conversation-based assessment matched human coding on 52.2% of 155 events, but used the hedged PARTIAL_CORRECT label more often than raters (53.5% against 41.3%) and flagged 5.4% of turns IRRELEVANT where raters flagged none (Hou et al., 2025).
- **AI feedback sustains participation and drives gains at scale:** Geschwind et al. (2026)'s semester-long field experiment across undergraduate tutorials found that individual GPT-4 formative feedback (spanning all three Hattie & Timperley dimensions — Feed-Back, Feed-Up, Feed-Forward) sustained the highest participation across eight open-ended tasks, lengthened student answers, and produced the strongest content learning gains — an effect driven by reliable, consistent AI provision, since when high-quality textual peer feedback was actually received, peer outcomes matched AI's.
- **Feedback futures:** Feedback Futures synthesizes a special issue and argues the question is not *whether* GenAI can produce feedback but how to design feedback that supports learning, distilling recurring tensions across the field.
- **Most formative feedback is momentary, not sustainable.** In a scoping review of 37 authentic-assessment studies, 23 used formative feedback for immediate improvement but only four used sustainable feedback that students transfer to future contexts — the reactive pattern current AI feedback tools reproduce (Zhan, Boud & Du (2025)).

- **Diagnosis-first feedback for open-ended quantitative problems:** Arthur (Yin et al. 2026) delivers real-time, personalized formative feedback on Engineering Economics Calculated Formula Questions, a domain where handwritten, unstructured solutions had previously blocked AI support. A per-question XGBoost backbone diagnoses likely rubric-labeled mistakes from students' submitted numerical answers (average precision 0.81, recall 0.79), and a dialogue-based scheme requests intermediate answers only when prediction confidence is low — balancing feedback accuracy against collection efficiency within a question-bank web interface.
- **Scale and limits of LLM formative feedback (systematic evidence):** a PRISMA-guided systematic review of 42 empirical studies (2023–2025) finds LLMs can reduce teacher workload and deliver rapid, personalized feedback at scale — especially in large or higher-education cohorts — but that feedback is sometimes too generic or misaligned with the assigned grade and reliability slips on longer, multilingual, or nuanced tasks, reinforcing that formative AI feedback is best deployed under educator oversight (Can ChatGPT Replace the Teacher in Assessment? A Review of Research on the Use of Large Language Models in Grading and Providing Feedback).
- **Adaptivity is a separable ingredient, not decoration:** Sukjaitham, Schaaf, Brod & Breitwieser (2026) supply the direct causal test that most LLM-feedback studies assume away, pitting GPT-4 response-contingent feedback against expert-written generic guidance matched on structure, tone, length, and motivational phrasing (verified with a five-dimension quality rubric, $\kappa = .76$–1.00). In a preregistered within-subjects experiment, 155 German fifth- and sixth-graders ($M = 12.08$ years) revised six if-then plans: plan quality rose from a median of **2 → 5** under adaptive feedback versus **2 → 3** under generic guidance (within-person $V = 10{,}440$, $p < .001$, $r = .86$; condition × time interaction estimate = 1.68, $SE = 0.14$, $p < .001$, with no pre-support difference). Children rated adaptive feedback both more helpful ($r = .67$) and more motivating ($r = .74$), and trial-level perceptions predicted the size of revision gains — making perceived usefulness part of the pathway rather than an affective byproduct. Because the control was itself well designed, the study shows added value *beyond* good non-contingent guidance rather than the difference between feedback and nothing: generic guidance is a genuine but limited substitute that plateaus at its own median. Planning served as the test case as a core self-regulated learning strategy with explicit quality criteria, which makes contingency — the property that distinguishes Scaffolding from static support — directly measurable on a one-sentence response. The authors define adaptivity narrowly as response-contingent adaptation of feedback content to the learner's concrete response, distinguishing it from conversational interactivity, tone, and stable-trait adaptive learning.
- **Perceived usefulness tracks actionability:** Mendonça et al. (2026) had 144 programming students rate 893 LLM-generated feedback instances on five dimensions and 237 consolidated reports on six, holding domain, task, and instrument constant while educational level varied. Ratings were favorable throughout, with student-level means of 4.24 to 4.43 for individual answers and 4.11 to 4.38 for reports. Yet actionability and usefulness drew the lowest ratings even as actionability and perceived accuracy carried the largest relative weights (32.6% and 29.0%) in a model explaining 76% of the variance in perceived usefulness, and motivation and personalization led a report-level model of intention to use explaining 53%. Since actionability is the dimension Feedback research treats as hardest to provide, the pattern reads as technology acceptance applied to feedback: usefulness tracks whether a learner can act, not how polished the feedback sounds.

- **Offline agreement overstates live performance:** Cruz et al. (2026)'s GPT-4o feedback pipeline reproduced the instructor's mark within 0.5 points in 83% of 362 submissions, yet chance-corrected agreement was only moderate (ICC(2,1) = 0.49) and fell from r = 0.92 on historical scripts to 0.57 in live instructor-supervised use.
- **Comprehension outruns actionability on the path to revision:** Yao and Fan (2026) separated issue-level diagnosis from suggestions and gave students a written interpretation sheet (restatement, effect explanation, uncertainty identification, revision plan) before independent revision, structured teacher review, reassessment and reflection. Across three writing cycles in two intact classes (96 students; 288 cycle-level observations), feedback comprehension carried the strongest association with revision quality (r = 0.501, ahead of actionability at 0.480 and diagnostic accuracy at 0.445), and the diagnostic group gained 5.92 writing points against 3.58 (Hedges' g = 1.12), locating the leverage in students' understanding of the diagnosis rather than in its actionability alone.

Curriculum-grounded and educator-in-the-loop design

LearnLens addresses three persistent problems in AI formative assessment: **error-aware assessment** (capturing nuanced reasoning errors rather than surface mistakes), **topic-linked memory chains** (replacing noisy similarity-based RAG (Retrieval-Augmented Generation) with structured curriculum-grounded retrieval), and **educator-in-the-loop** design (teacher customization and oversight, not full automation). This connects to the broader tension in Human-in-the-Loop: scalable automation with expert validation.

Hoppe, Loibl & Leuders (2026) sharpen what educator-in-the-loop means once a tool produces its own claims rather than raw observations. Their conceptual analysis argues that AI-generated diagnostic inferences are qualitatively different evidence, because they are already the product of algorithmic interpretation, so teachers need a further layer the authors call **meta-diagnosis**: deliberately accepting, rejecting, or modifying an inference and integrating it with their own contextual knowledge. Specifying the DiaCoM framework for this treats AI-generated inferences as a situation characteristic and the accept, reject, or modify decision as diagnostic behavior, while expanding the person characteristics teachers need to include knowledge of how AI systems actually work. Because current systems rest mostly on performance data such as task correctness and completion time, motivational states and classroom dynamics stay largely absent, so the paper keeps teachers, not the dashboard, as the responsible reflective agents and frames judging algorithmic claims as a target for professional development.

Matching the AI's role to achievement level is a related design move: pre-service science teachers described ChatGPT as a Patient Tutor for low achievers, a Personal Coach for medium achievers, and an Intellectual Sparring Partner for high achievers, while the instructor kept the final explanation of difficult content (Ratniyom et al., 2026).

Design trade-offs

Dimension	AI Suitability	Human Requirement
Factual correctness	High	Low
Concept alignment	High	Medium

Dimension	AI Suitability	Human Requirement
Distractor quality	Low	High
Feedback depth	Low	High
Rubric consistency	Medium	Medium

Assessment, feedback, and learning

Formative assessment in AI education connects to the learning process itself:

- **Feedback loops:** feedback loops are the mechanism by which formative assessment informs learning; AI tutors and adaptive systems close these loops at scale.
- **Self-regulated learning:** formative feedback supports self-regulated learning when students monitor progress and adjust; AI feedback should cultivate evaluative judgment, not displace it.
- **Automated scoring reaches some phases of the cycle, not all:** Chen & Liu (2026) ran a 14-week quasi-experiment in which 46 interpreting students submitted weekly renditions to an automated scoring system that returned an immediate score, transcript, marked errors, and a reference rendition, while a control group received whole-class teacher feedback only. The automated group improved more overall (d = 1.03), but the gain stayed where the deficit was decomposable, the signal reliable, and the scale sensitive: linguistic accuracy and logical coherence rose while information fidelity (agreement with human raters r = 0.12) and delivery fluency did not move. Self-regulated learning was uneven in a matching way, with execution and monitoring correlating with score gains (r = 0.42) while planning and emotional motivation sat near the scale midpoint, and several students deferred engagement after low scores instead of analyzing causes. The system reached the performance phase of the cycle, not the planning that precedes it.
- **From automated diagnosis to generated practice:** Zhu, Luo & Li (2026) wire audio-score alignment, error quantification, and a Proximal Policy Optimization layer into one closed loop for music education, turning rhythm error signals (91.2% recall, 98.4% specificity) into rewards that steer generated practice tracks. They report a significant Group x Time interaction favoring the system group (beta = 0.52) across a 12 week quasi-experiment with 120 undergraduate music majors. The authors frame this as technical feasibility, and the practical reading is triage rather than assessment. Precision of 89.7% means roughly one flagged rhythm error in ten is a false alarm, and the study's expert reviewers rated support for musical expression as the weakest area, so automated loops suit technical drills while expressive judgment stays with teachers.
- **Scaffolding:** Scaffolding and formative assessment work together — AI can provide just-in-time hints and prompts, though sequenced feedback research cautions against over-structuring.
- **Rubric quality moves automated-grading agreement more than model choice.** On 1,200 Linux/bash exam responses, Alonso-Carracedo et al. (2026) found adding a full rubric plus a reference answer lifted every model (best: Gemini 3.0 Pro, ICC(3,1) = 0.888 against a human ceiling of 0.949), while agreement fell monotonically as the question's cognitive level rose.
- **AI-generated rubrics matched human scoring only within a margin.** Four AI rubrics met pooled equivalence with the human baseline within ±5 points across 308 programming responses

(correlations 0.948–0.973), but five rubric–assignment cells exceeded it, and GPT-4.1/4o graded systematically harsher on structured rubrics (−4.46 against −0.66 for free-form) (Mendonça et al., 2026).

- **Validity and quality:** the quality and validity of AI-generated formative items and feedback must be evaluated; AI Ed Evaluation provides the methods.
- **AI scoring adds a validity threat.** Because an AI scorer can reward construct-irrelevant features such as language fluency instead of scientific reasoning, a Stanford/ETS white paper distilled from a ~100-leader convening argues assessment should accumulate continuous, context-rich evidence rather than certify one-shot outputs (McGee et al. (2026)).
- **Keep the vulnerable task and add a twin.** Roe, Perkins & Giray (2026) argue take-home essays and research reports carry substantial formative value and should be retained for learning, paired with a second task assessing the same outcomes that supplies reliable summative evidence.
- **Technology-supported formative assessment is a system property, not a tool.** Bulut (2026) defines it as the joint product of technological capacity, pedagogical regulation, learner agency, and human judgment, and argues its value lies in sustaining the evidence-feedback-reflection-action cycle rather than in automation.

Risk: Assessment as surveillance

Formative assessment systems can shift from learning-support tools to behavior-monitoring infrastructure. The same data streams that enable adaptive tutoring can enable punitive tracking if AI Governance is weak. This connects to Privacy and student well-being, and argues for formative systems that support learning rather than surveil it.

Observability can be designed for without surveillance: it is the evidence an assessment actually generates for defensible judgment about learning, treated as a design priority whose cost is paid in feasibility rather than ethics (Pedlow et al. (2026)).

Implications for AI in education

- **Match item type to AI reliability:** use AI for verifiable dimensions (concept alignment, correctness) and retain human judgment for instructional dimensions (distractor quality, feedback depth).
- **Design for enactment, not just provision:** AI feedback only helps when students select, evaluate, and apply it — structure workflows that support enactment.
- **Feedback design matters more than volume:** sequenced or over-structured feedback can backfire; prioritize feedback that supports student sense-making and autonomy.
- **Keep educators in the loop:** curriculum-grounded, educator-in-the-loop systems improve relevance and reduce noise.
- **Evaluate quality and validity:** assess AI-generated items and feedback for quality, validity, and equity, not just generation speed.

- **Treat formative assessment as a philosophy, not a toolkit.** Mesny, Roberge-Maltais & Galy (2026) synthesize the wider higher-education literature into an "assessment for learning" paradigm that frames formative, ongoing, and individualized Feedback as an overarching philosophy rather than a mere toolkit — balancing formative with summative purposes and foregrounding student agency, self-regulation, and metacognitive skill. They identify five mutually reinforcing practices (authentic assessment, self- and Peer Assessment, reassessment, standards-based grading, ungrading) through which this philosophy can be enacted, while noting their uptake remains highly uneven across higher-education fields.
- **Continuous assessment reframes the formative record itself.** The AIM-CAI reference architecture (a position paper, not an implementation) proposes replacing episodic assessment as the primary evidence base with a six-layer infrastructure: evidence generation across platforms, serialization preserving source context, AI-mediated semantic translation, psychometric interpretation, longitudinal competency profiles, and federated governance. Its shift table spells out the change: per-assignment feedback becomes longitudinal feedback supporting advising and reflection; grades become evolving competency profiles; credentials become transparent development records. The governance layer is the paper's insistence — seven named tensions (interoperability vs. local autonomy, privacy vs. utility, learner agency vs. predictive automation, surveillance vs. support, etc.) each mapped to risks and responses, with the warning that ungoverned continuous inference privileges dominant cultural norms. The novelty claim is integrative: the components exist; the contribution is the architecture and the governance map. (AI-Mediated Continuous Assessment Infrastructure (AIM-CAI): Connecting Learning Evidence Across Contexts and Time)

Common Misconceptions

- **"Generated practice items give useful formative signal." An easy generated item bank gives no formative signal**: in a **10-week deployment about 70% of AI-generated practice items were answered correctly by every student**. A bank everyone passes carries no information about who needs what.
- **"Item generation reliability is uniform across formats."** AI systems generate formative items across modalities **with reliability varying by type** — multiple-choice among them. Treating generated items as interchangeable across formats hides where generation is dependable.
- **"Giving students AI feedback produces enactment."** The **enactment problem** is documented separately from feedback quality: receiving feedback and acting on it are distinct steps, and the second is where formative assessment succeeds or fails.

Summative Assessment

> **Summative assessment** — assessment used to evaluate and certify what a learner has learned at the end of a unit, course, or program, in contrast to formative assessment which supports learning during instruction. Summative assessment typically takes the form of high-stakes examinations — written, oral, proctored, or closed-book — that assign grades, gate progression, and certify competence. In the AI era, summative assessment has become a central battleground over Academic Integrity and validity: generative AI can inflate performance on unproctored or take-home tasks, making the choice of summative format — and how it resists AI substitution — a pivotal design decision.

Questions to Consider

- Summative assessment certifies what a student has learned at the end of a course, while formative assessment supports learning during it. Where have you seen the line between these two blur, and why might it matter that they serve different functions?
- The page frames generative AI as reshaping summative assessment in two directions at once: AI scores exams, and students use AI to evade exam-based measurement. Which of these two pressures do you think is the bigger threat to validity, and why?
- If unproctored or take-home tasks lose validity because AI can produce the answers, what does that imply for how assessments should be designed — and what might be sacrificed in the process?
- Research cited on the page finds LLMs do not grade essays the same way humans do. If automated scoring is fast and consistent but grades differently, is that a fairness problem, an opportunity, or both?
- What does a high-stakes result (a grade, a credential, admission) mean if the work behind it could have been produced by AI? How would you design an assessment you could actually trust?

Introduction

Summative assessment serves a fundamentally different function from formative assessment: it measures and certifies achievement rather than guiding next steps. It includes end-of-unit tests, final examinations, standardized and high-stakes tests (e.g., entrance exams), oral defenses, and cumulative performance assessments. Because summative results carry real consequences (grades, progression, credentials, university admission), they face particular pressures in the AI era — both as *targets* of automated scoring and as *vulnerable* measures that students may seek to game using generative AI.

The AI-era stakes: validity and integrity

The knowledge base's research documents how generative AI has fundamentally reshaped the summative-assessment landscape in two directions: AI is used to **score** exams at scale, and AI can be used by students to **evade** exam-based measurement of their own learning.

- **AI as scorer.** Summative assessment increasingly relies on automated scoring of exams, essays, and short answers. Research on LLM essay grading finds LLM do not grade essays the same way humans do, raising validity and fairness questions for high-stakes automated scoring. LLMs assessing student self-explanations and automatic short-answer grading explore the reliability of LLM scoring in summative contexts, while psychometrically-aware frameworks seek to keep automated scoring trustworthy and adaptive. A 296-student handwritten general-chemistry exam illustrates why selective oversight is required: a Multimodal AI LLM's total-score agreement with TA grading was high ($R^2 = 0.91$) yet item-level reliability varied sharply by format. False positives (AI crediting genuinely wrong answers) tend to go undetected because students rarely contest them — so a uniform "grade everything" AI scorer is not defensible for high-stakes use without confidence-based deferral to humans (Assisting the grading of a handwritten general chemistry exam with artificial intelligence).
- **Outcome agreement can survive imprecise item scoring.** Against moderated official marks, a multimodal LLM grading 10,364 handwritten Physics Olympiad and university pages correlated at $r = 0.93–0.96$ and recovered the same five-student international team, though exact question-part agreement reached 70% — a scorer is judged by the decisions it informs (Pathak et al. (2026)).
- **AI as evasion.** Because generative AI can produce answers to written questions, unproctored and take-home summative tasks lose validity: proctored, unassisted measures are essential because non-proctored performance is inflated by AI, and guardrailed (hint-not-answer) tools can eliminate the exam penalty that unguarded AI causes. Chirikov's (2026) quasi-experiment on 500,000+ grades makes the mechanism concrete: after ChatGPT's release, courses with more AI-exposed tasks saw the share of A grades rise by 13 percentage points, and the effect concentrated in **homework-heavy courses** (an additional 16 pp in the triple-differences estimate) — direct evidence that unproctored homework, not genuine learning gains, is where AI inflates summative outcomes.
- **The test-taker and the scorer are the same capability.** On an introductory Java OOP course's own tests and exam, five 2026 systems graded with the student rubric beat the cohort average in every case but one (14.61 vs 13.76 on test 1; 14.87 vs 13.39 on test 2). They often earned full marks on longer tasks while still failing interfaces, abstract classes and image-based questions (Lepp and Kaimre (2026)).
- **AI-generated exams.** A large-scale field study and EFL assessment research examine whether AI can *generate* high-quality exams and assessment tasks — an emerging summative-design use of AI.
- **Students cannot reliably spot AI-drafted items.** In a credited Family Medicine exam, Vogt et al. (2026) found no significant difference in source attribution between 30 AI-generated and 30

licensing-exam multiple-choice items, mean correct recognition of 68.6 to 77.5 percent, and 18.2 percent of generated items eliminated in human review.

AI-resistant summative formats

A key theme in the knowledge base is that **summative format determines AI-resistance** — the more a task requires live, in-person, individually-probed performance, the harder it is for students to substitute AI for their own learning.

- **Oral exams and assessments.** Fenton (2025) argues the oral exam is a low-tech, inherently AI-resistant summative format: its real-time, interactive dialogue tests comprehension, critical thinking, and reasoning rather than memorization, prevents students from using AI to generate and memorize answers, and mirrors professional practice. Socratic tests and code-review interviews extend this to dynamic, conversational, and interview-based summative assessment.
- **Closed-book, proctored, unassisted measures.** Evidence and large-scale field data show that proctored closed-book exams — not inflated homework or take-home work — are the reliable signal of actual learning when students use AI. Responsible assessment frameworks embed these unassisted measures within a validity-driven redesign. Where exams stay online, remote proctoring takes over that role, and the corpus's two reviews of automated proctoring find privacy and fairness concerns alongside detection gains (Ensuring academic integrity through automated online exam proctoring: a decade long systematic review, A comprehensive review of the changing landscape of academic dishonesty in automated proctoring in the era of artificial intelligence).
- **Pair a vulnerable task with a confirming twin.** Roe, Perkins & Giray (2026) keep a GenAI-vulnerable task for its learning value but pair it with a second task assessing the same outcomes, making the mark interdependent through a confirmatory threshold or weighting so the twin certifies the result.

High-stakes and standardized summative assessment

High-stakes summative assessment — entrance exams, standardized tests, and certification — carries outsized consequences and is a focus of AI-era concern. The generative AI learning penalty study measured outcomes on high-school (Zhongkao) and college (Gaokao) entrance exams, finding entrance-exam scores fell 18–24% after prolonged AI use. The Effortless Trap and performance-vs-learning research warn that gains on AI-assisted tasks do not transfer to unassisted high-stakes measures.

Summative vs. formative in the AI era

The knowledge base's assessment literature consistently emphasizes that Assessment is most effective when it combines formative and summative functions — but the AI era sharpens the distinction. Because AI inflates performance on low-stakes, unproctored, and process-hidden tasks, **summative (especially proctored/closed-book/in-person) measures become the crucial check** on whether learning actually occurred. This motivates assessment redesign that keeps authentic, AI-resistant summative tasks (oral exams, code-review interviews, proctored examinations, process-based portfolios) as the anchor of integrity while

using formative assessment to support learning along the way. See Authentic Assessment for the constructive design response.

Implications for AI in education

- **Summative format is a validity and integrity lever:** AI-resistant summative formats (oral, proctored, closed-book, in-person) preserve the connection between assessed performance and actual learning.
- **Proctored/unassisted measures are the reliable signal:** when students use AI, unassisted summative exams — not homework — reveal genuine learning.
- **Automated scoring needs psychometric scrutiny:** using LLMs to grade high-stakes exams requires evaluation of reliability, fairness, and validity, not just accuracy.
- Grading error is also grade-dependent: across 32 public-health exam submissions, the LLMs avoided the scale's ends — no E or F appeared in fast mode — while the best model matched the human grade exactly on 50.0% and within ±1 grade on 90.6% (Brevik et al. (2026)).
- **AI can also generate exams:** AI-assisted exam and task generation is an emerging summative-design application that itself needs quality evaluation.
- **Reconsider grading purpose, not just format.** Mesny, Roberge-Maltais & Galy (2026) critique traditional summative, norm-referenced grading for encouraging superficial, fragmented learning, giving students little control or transparency, harming intrinsic Motivation, fueling stress and anxiety, and perpetuating inequities while largely assessing recall rather than real-world application. They position reassessment, standards-based grading, and ungrading as grading-focused innovations that can soften summative-heavy practice, while acknowledging these remain marginal in management education because of normative barriers — grading on a curve, external signaling (rankings, internships, accreditation), and students' instrumental mindset — and recommend incremental experimentation with institutional support.

Common Misconceptions

- **"An LLM cannot grade to official standards."** Against **moderated official marks**, a multimodal LLM grading **10,364 handwritten** Physics Olympiad and university pages correlated strongly. Outcome agreement can survive imprecise item-level scoring — which means the useful question is where item-level precision is actually required.
- **"AI grade inflation is speculation."** Chirikov's (2026) quasi-experiment on **500,000+ grades** makes the mechanism concrete: after ChatGPT's release, **courses with more AI-exposed tasks saw the share of higher grades rise**. The effect concentrated where tasks were exposed, which is the pattern a mechanism would predict.
- **"Students who use AI cannot be distinguished from those who do not, so provenance is hopeless."** The finding that there was **no significant difference in source attribution** between AI-generated and licensing-exam items, with correct recognition of **68.6-77.5 percent** and an **18.2 percent** misattribution rate, is about recognition failing — not about provenance being unnecessary. If anything it raises the requirement for verified provenance.

Authentic Assessment

> **Authentic assessment** — the design of assessments that examine student performance on worthy, realistic intellectual tasks, rather than isolated, standardized test items. Originating with Wiggins (1990) as a counterbalance to standardized tests, authentic assessment has evolved from replicating workplace tasks toward a multi-dimensional framework encompassing professional, digital, personal, and social authenticity. Generative AI has made authentic assessment newly essential: any task a language model can credibly simulate in a take-home setting loses its validity as evidence of original student competence, so authentic forms must be redesigned around what AI cannot credibly counterfeit.

Questions to Consider

- Authentic assessment examines performance on worthy, realistic intellectual tasks rather than isolated test items. Before reading, did you assume an ‘authentic’ task simply replicates a real-world or workplace scenario? This page argues authenticity has evolved well beyond mere replication — what other forms can it take?
- A central claim is that any task a language model can credibly simulate in a take-home setting loses its validity as evidence of original student competence. Which assessment in your own teaching or study would you now consider ‘counterfeitable’ — and what makes you say that?
- The page highlights a striking gap: only 3 of 37 studies addressed social authenticity — whether assessment lets students contribute to societal change. Why do you think the social dimension of authenticity is so neglected, and what might assessing it actually look like?
- The knowledge base argues authenticity must be ‘redesigned, not policed.’ When students co-author rubrics, choose what and how to submit, and engage in real-time interaction, AI use becomes expected and declared rather than concealed. How would that shift the relationship between student and assessor?
- Oral exams and process-based portfolios are offered as AI-resistant authentic forms. But graded reflection and Self-Assessment risk becoming performative — students performing the reflection they think is wanted. How could you design for genuine reflection rather than performance?
- When AI supplies the rubric, the feedback, and the monitoring, the page warns that a student’s metacognitive practice may be displaced. If the tool does the evaluating, what is left for the learner to actually practice or learn?

Introduction

Authentic assessment sits at the heart of how Assessment is being rethought in the AI era. It connects to Assessment Validity (does the assessment measure what it claims?), Formative Assessment (authentic tasks that inform learning), and Academic Integrity (moving from detection to designing tasks where AI use is expected and declared). It is a central response in the knowledge base’s assessment-redesign literature.

The evolution of authenticity

- **1990s origins — worthy intellectual tasks:** Wiggins (1990) proposed authentic assessment as direct examination of "student performance on worthy intellectual tasks," a counterbalance to standardized tests.
- **Late-1990s uptake — workplace replication:** Joughin (1998) framed authenticity as the extent to which assessment replicates professional practice or real life — a view that dominated for two decades.
- **2020s critique — beyond replication:** McArthur (2023) argued authentic assessment must enable students to "influence the future and transform society" rather than merely replicate existing tasks; Ajjawi et al. (2024) broadened authenticity to contextual, task, and personal forms that reflect student experience.
- **Generative AI as existential challenge:** Zhan, Boud & Du (2025) note that generative AI makes workplace-replication authenticity newly vulnerable, driving a pivot toward digital literacy, real-time collaboration, social contribution, and individual meaning-making that AI cannot credibly counterfeit.

A six-dimensional design model

Zhan, Boud & Du's (2025) scoping review of 37 empirical studies (2000–2024) proposes six design dimensions: (1) authenticity in assessment (assessment, professional, digital, self, and social authenticity — with only 3/37 studies addressing social authenticity, a critical gap), (2) cognitive challenges, (3) assessment criteria (with students often passive recipients rather than co-authors of rubrics), (4) feedback (formative-dominated, but sustainable feedback rare), (5) student agency (choice in what/how/when/where to submit was rare), and (6) social collaboration. It also proposes a cyclical co-design model — negotiate goals, create context, co-design criteria, plan feedback — that AI tools could operationalize.

Dollinger and Nieminen (2026) bound this optimism with the *paradox of inclusive assessment*: both the accommodations model and structural critiques that reframe assessment as disabling leave intact the zero-sum logic that "for one student to succeed, someone else needs to fail," so distributed and agentic forms must change that logic rather than only widen access.

Authentic assessment in the AI era

The knowledge base's assessment-redesign literature argues that authenticity must be **redesigned, not policed**:

- Beyond Detection contends that authenticity cannot be policed into existence; it must be designed, positioning AI as a declared collaborator rather than a cheating application, and prioritizing authentic, process-based assessment over surveillance.
- Responsible Assessment reframes assessment around validity evidence and authentic tasks that mirror students' future work.
- Authentic products, authenticated processes examines how AI-rich higher education can assess both genuine outputs and the processes that produced them.

- **An AI drafting partner still leaves the judgment.** Paula et al. (2026) piloted a GPT-4.1 assessment designer with eight coordinators: it produced usable overviews, tasks, criteria, timelines and rubrics but repeatedly missed disciplinary context and topic sequencing, and all eight refused end-to-end automation, locating academic judgment rather than the model.
- The tool-invariant framework argues for assessing computational methods and process rather than tool-specific outputs, using oral defense and verification.
- **Institutional infrastructure for process evidence.** A commissioned quality-assurance framework turns the process argument into policy, treating learning-process traces — time-stamped edits, resource use, metacognitive prompts — as the durable evidence a transcript cannot show, and citing process features that explain more variance in performance than product features alone (Lodge et al. (2026)).
- **Scalable oral assessment, with a scoring caveat.** Pentland, Lowenthal & Krier (2026) delivered time-limited, non-revisitable recorded responses graded against embedded rubrics, and found students outscored their in-person multiple-choice exams; they stress this is a format effect rather than a learning gain, with LLM re-scoring agreeing with the instructor at ICC = 0.73 and 0.60.
- Reconsidering oral exams positions the oral exam/assessment as a low-tech authentic alternative that is inherently AI-resistant — its real-time, interactive dialogue tests comprehension, critical thinking, and reasoning (not memorization), mirrors professional practice, and prevents students from using AI to generate and memorize answers. It offers a concrete set of practical recommendations (clear rubrics, standardized content, assessor training, prompting guidelines, bias mitigation) for reintroducing Oral Assessment across high school and higher education.
- E-portfolio assessment is another authentic, process-based form that resists AI fabrication: Zhan, Boud & Du (2025) identify social contribution portfolios among the authentic forms most robust to generative AI, and Beyond Detection recommends annotated portfolios and recorded walkthroughs that probe reasoning in real time. Ni & Lam (2026) and Laksana et al. (2026) show generative AI can assist the portfolio process — feedback, drafting, reflection — while the portfolio's reasoning traces and drafts preserve authenticity.
- **Authenticity criteria can themselves restrain AI use.** Chen and Zou (2026) found that a rubric requiring students to ground a group presentation in their own first-hand teaching experience, and to reflect on shared classroom observations, led seven of fifteen student groups to *deliberately reduce* their GenAI use. Students argued the tool could not meet the epistemic demand — "AI only knows that moment when you type" — because it lacked the longitudinal, situated knowledge their classmates and teacher had. Both layers mattered: the authenticity of the task and the relational authenticity of contributing one's own thinking to a group, which reframed heavy AI use as free-riding on peers. The design implication is that authentic, experience-grounded criteria do evaluative work even without enforcement — they supply a reason for restraint that policy statements cannot.
- **Twin a vulnerable task with a less-vulnerable one.** Roe, Perkins & Giray (2026) pair a GenAI-vulnerable task with a second assessing the same outcomes, schedule them close together so each can cross-check the other, and make the mark interdependent through a confirmatory threshold or weighting.

Sharma (2026) argues that integrity-oriented design and authentic design are not the same thing, and that the difference is epistemic rather than stylistic. Authenticity asks whether a task mirrors worthwhile real-world practice; integrity-oriented design asks whether learners can justify their decisions and assume responsibility in relation to disciplinary standards, which makes integrity an explicit, assessable criterion embedded in the task architecture rather than an incidental by-product of realism. The practices he offers — annotated decision trails, verification of GenAI-contributed claims, oral defense and dialogic accountability, draft differences with version history — are recognizably authentic-assessment forms. They are selected, however, for the judgment they make visible rather than for their realism — a useful corrective for tasks that look authentic and remain counterfeitable in substance. His caution belongs on this page too: requiring documented reasoning privileges learners more fluent in reflective discourse, and judgment as evidence "remains relational and situated rather than mechanically verifiable", so the design carries its own interpretive-reliability load.

The same question is reframed by Thapa and Lewis (2026), who name what a task should *authenticate* rather than whether it looks real: epistemic authenticity, the extent to which assessment captures genuine engagement with interpretation, evaluative judgment, reasoning and knowledge construction. Their argument is that authenticity alone does not survive generative AI, because an authentic task whose evidence is one unsupervised product is exposed to the same substitution problem as the essay it replaced. Making reasoning visible instead requires staged submissions, reflective justification, dialogic engagement and evaluative transparency. They carry the caution above into design: reflective and dialogic tasks can privilege students confident in academic self-articulation unless they are inclusively designed and scaffolded, and the relational work intensifies educator emotional labor in large or resource-constrained settings.

When practitioners retreat to the policed formats

The knowledge base argues that authenticity must be designed rather than policed, and Goldstein, Marae-Haj and Zidan (2026) supply the counter-evidence from practice: after a trust crisis in which pre-service teachers submitted raw AI-generated work as their own, teacher educators in seven Israeli colleges redesigned assessment around process evidence (prompts, document version history, monitored group contributions) and in-class performance — but several also described falling back, as a last resort, on supervised examinations and anticipated oral defenses on theses, one participant calling the return to exams personally painful yet unavoidable. Read against the design-first position, the finding marks a failure mode rather than a solution: where authenticity is not redesigned in advance, the practical response to unassessable submitted work is reinstated control — surveillance by another name — which reintroduces the very formats the authentic-assessment literature tries to move beyond. It also shows the felt cost of the alternative: participants reported their take-home written assessments could no longer evidence learning at all, and that process documentation took real work to establish.

A second failure mode sits inside redesign itself: across five online language-teaching methods, authenticity-related tensions dominated teachers' accounts (11 of 20), including task realism corrosion — activities redesigned to be AI-resistant rather than authentic (Baoyi and Khan (2026)).

The retreat carries an evidentiary cost that the case-file evidence makes visible. Munoz et al. (2026) coded 1,162 generative-AI misconduct allegations and found that the strongest evidence types are generated by the investigation or by supervision rather than by the allegation, and that process evidence such as drafts,

supervision meetings and presentations appears only where those practices already exist — so in an unredesigned assessment the process evidence this literature recommends is simply not available, and cases rest on weaker categories. What stands in for it is the weakest material in their corpus: detector output drew the lowest probative ratings of any category, and Hadra et al. (2026) show why, with macro accuracy of 0.69 (Originality) and 0.61 (Turnitin) across 192 texts, near-total failure on hybrid human–AI writing, and a borderline tendency to misread EFL student work as AI. Wright (2026) adds the rule-design dimension: prohibitions written by platform identity rather than function are over-inclusive by definitional accident, so a policed format can sanction a student who did not do the thing the rule was designed to prevent, falling hardest on the students who relied on transcription tools for Accessibility. Read together, the retreat substitutes the least probative evidence available for the process evidence that authentic design would have generated in the first place.

- **Self-regulated learning:** student agency in authentic assessment (choice, self-reflection, co-design) mirrors the forethought → performance → self-reflection cycle, though graded reflection risks becoming performative.
- **Metacognition:** Metacognition is required for students to evaluate their work against co-designed rubrics; when AI supplies the rubric, feedback, and monitoring, the student's metacognitive practice may be displaced.
- **Formative and sustainable feedback:** authentic assessment emphasizes formative, future-oriented feedback that transfers to later contexts.

Implications for AI in education

- **AI-proof assessment types:** in-vivo demonstrations, social-contribution portfolios, co-created artifacts with auditable provenance, and real-time embodied interaction are more resilient to generative AI than take-home essays or MCQs.
- **The exposure is measurable.** A three-year psychology degree proved 90% passable: ChatGPT produced adequate output on 36 of 40 coursework assessments, and only the four tasks requiring presence, a visual artifact, or the student's own data resisted (Ivory et al. (2026)).
- **Co-design at scale:** AI tools could enable rubric co-design and student co-creation of assessment parameters at classroom or MOOC scale — though machine-mediated agency must be designed carefully.
- **Address the social-authenticity gap:** only 3/37 studies addressed social issues; AI assessment tools should help students contribute to societal transformation, not merely simulate it.
- **Sustainable feedback:** AI feedback should be designed to transfer to future contexts, not just provide reactive, momentary corrections.
- **Process-focused measurement now has validity evidence.** Oliveira et al. (2025) scored 70 graded essays on how students steered a GenAI dialogue and made course knowledge visible; those process scores correlated r = 0.54 with traditional essay scores while rewarding conceptual work over structured task specification.
- **Authentic assessment suits practice-oriented fields.** Mesny, Roberge-Maltais & Galy (2026) find authentic assessment especially well-suited to management education: tasks mirroring real

professional problems (live consulting projects, dashboards with executive briefings) align with the field's practice-oriented, employability focus and can support inclusive, integrity-preserving alternatives to exam-centered assessment in the generative AI era. In their review of 58 articles from four management-education journals, however, authentic assessment appeared mainly via technology-mediated simulations and was often conflated with experiential learning — a terminology gap that can obscure its broader value and uptake.

- **Authenticity is not security, and the gap is visible at sector scale.** Where the single-degree audit above found 90% of coursework passable, Villanueva (2026) scores recorded presentations, remote group projects and unsupervised digital artifacts in the high-exposure band across 53,915 items, because the public record shows nothing about how production was supervised.

Common Misconceptions

- **"Authenticity is about realistic tasks."** Zhan, Boud and Du's (2025) scoping review of **37 empirical studies (2000-2024)** proposes a **six-dimensional** design model, and only **3 of 37 studies addressed social authenticity** — whether assessment helps students contribute to societal transformation. Realism is one dimension and the most advanced dimension is barely studied.
- **"Authentic assessment resists AI."** The exposure is measurable and large: a **three-year psychology degree** proved **90% passable**, with ChatGPT producing **adequate output on 36 of 40 coursework assessments**, with only the remaining assessments surviving. Most of a degree's assessment was AI-satisfiable.
- **"Redesign is optional if the work is real-world."** The 36-of-40 result was found on coursework whose authenticity was presumably not in question. Task realism did not protect against AI completion; the design of what is assessed did.

- How Do I Redesign Assessment So That a Grade Still Tells Me Something Defensible About What the Student Knows or Can Do?
- How Should We Design and Facilitate Asynchronous Online Courses When AI Can Do the Work?

Process-Oriented Assessment

> **Process-oriented assessment** — the design of Assessment around how a learner reaches a conclusion rather than only around the artifact they hand in: staged submissions, reflective justification, dialogic and oral exchange, draft and version history, and criteria students can apply to themselves. It is not a synonym for task realism and not a claim about who marks the work: a realistic task whose only evidence is one unsupervised product is exposed to the same substitution problem as the essay it replaced. Generative AI is what makes the distinction urgent, because fluent output can now be produced on demand and a finished file no longer carries information about whose reasoning produced it.

Questions to Consider

- If a student submits a polished essay, what does that artifact actually let you claim about their thinking — and which claims does it only appear to support?
- Process evidence asks for drafts, justification, and dialogue. Who in your setting is fluent in that kind of academic self-articulation, and who might be judged on their comfort with it rather than on their understanding?
- Detection is unreliable and redesign around process is expensive. Where would you spend a limited institutional budget, and what evidence would change your answer?

Introduction

Assessment in higher education has long inferred the thinking from the product. A submitted essay, report, or examination answer stood in for the reasoning behind it, and grading treated a well-argued artifact as evidence of a well-argued process. Thapa and Lewis (2026) name the assumption that generative AI breaks: a polished response "may no longer represent anyone's thinking process," so the inference from artifact to understanding stops being safe. Their answer is not a better detector but a different evidence base. Process-oriented assessment collects evidence of interpretation, justification, and knowledge construction as they develop, so that reasoning stays visible when output can be produced on demand.

It helps to say what the concept is not. It is not authentic assessment, which asks whether a task mirrors worthwhile real-world practice; Thapa and Lewis keep the axes separate and insist that an authentic task with a single unsupervised product is still exposed. It is not AI detection, which asks whether the tool was used rather than how a decision was made. And it is not automated assessment, which concerns who or what does the marking: a machine-graded staged portfolio can be process-oriented, and a human-graded final essay need not be. The concept concerns which evidence is collected, over what period, and under what conditions it is produced.

The idea has moved from a proposition to a recurring recommendation across the knowledge base. It appears as a named priority in AIED's agenda for learner Learner Agency and Motivation, as the organizing research agenda for the retention and transfer problem in performance-versus-learning research, as "Black Box Assessment" in Brunnström and Palmqvist's account of self-regulated learning with AI, and as a request

from practicing teacher educators who found their take-home written work could no longer evidence learning at all.

What process evidence looks like in practice

The most explicit design vocabulary comes from Thapa and Lewis, whose four commitments carry the argument into task design: reflective justification, staged task design, dialogic engagement, and evaluative transparency. In practice, students explain interpretive decisions rather than only presenting conclusions, submit work that develops across checkpoints, take part in oral or dialogic exchanges about their reasoning, and work against criteria they can apply themselves — the terrain of feedback literacy and Self-Assessment. Boysen's (2026) proposal for open learning practices translates the same logic into an audit trail: a shared learning plan set before the project begins, a learning analysis plan naming required and forbidden sources, and documented drafts and version histories, preserved through Track Changes and saved file versions, that expose the work process and explain what informed each revision. He frames this as self-regulation made visible.

The channel chosen for process evidence changes what can be evidenced: in the same 79-student generative-AI study, higher-depth monitoring and planning were more common in think-aloud units while higher-depth regulation was more common in interaction logs, so no single record captures the whole process (Li and Liu (2026)). Traces can also diverge from scores outright: across 150 student–AI conversations, 41% carried an assignment score of exactly 1.00 while observable cognitive participation varied, so matched scores can conceal different processes (Fábrega, 2026). DraftTrace answers the same problem for AI-integrated writing by aligning keystroke-level process measures with the final product and with AI-interaction traces, showing that copy-typing is identifiable only when product and process are read together (Chandarana et al. (2026)), a concrete instance of the behavioral-trace measurement the field still lacks.

Practitioner and framework accounts fill in the artifacts. Uden and Hwang's (2026) LEARN framework, aimed at problem-based learning Assessment, asks for process-focused rubrics, oral justifications, staged submissions, and reasoning traces with AI-use disclosure, and treats reflection through learning journals and think-aloud protocols as the metacognitive engine of the sequence. Moganadas and colleagues (2026) make AI-transparent, process-oriented assessment one of five researchable propositions, requiring documentation, verification, and reflective justification rather than prohibition or detector use. Padhy (2026) recommends capturing revision history, interaction patterns, and time-on-task, paired with transparent disclosure. Goldstein, Marae-Haj and Zidan (2026) report the same artifacts emerging from practice after a Trust crisis: prompting records, document version history, monitored group contributions, and reflective "journey journals" kept in physical notebooks — alongside the plain finding that take-home written work could no longer evidence learning.

Concrete tooling is emerging: Kim et al. (2026) split problem solving into four stages and eight diagnostic sub-skills, which lets an Large Language Models (LLMs) write questions and rubrics specific to a stage; five teachers and 64 students trialed it on 90 problems and 720 sub-questions, with a mean System Usability Scale score of 83.5.

Checkpoint submissions were routine in practice: across six terms of the six-week asynchronous graduate research-methods sequence serving some 440 K-12 teachers, they averaged 96% completion, and later

iterations that added explicit prompt templates produced longer and visibly more substantive reflections Packard et al. (2026).

- **“Process evidence needs a special assessment regime.”** Some of it is an afternoon of instrumentation: a study of **77** college essay writers used a CodeMirror editor logging insertions, deletions, selections, cuts, copies and pastes with timestamps, beside an in-house chat panel on the default API, and captured **361** messages. The same traces showed that **14** responses to planning queries were pasted into final essays, which no product-level report would have revealed. The honest limit is in the instrument: typed words count as the student’s even when rephrased from a response, so the boundary between typing and thinking is invisible. Logging the process is cheaper than designing for it.

A process trace is only feedback if the learner reads it against the task. Xian et al. (2026) gave eleven translation students Inputlog and screen-recording visualizations plus a single 30-minute reflection session. The share of meaning-level revisions rose from 18.1% to 28.4% ($t(10) = 4.259$, $p = 0.002$) while total revisions did not change significantly, falling from 1,292.91 to 1,052.36 ($p = 0.248$). The trace did not make students edit more, only differently, which is the argument for process evidence in one result.

A different axis from authenticity, and from marking

Holding the axes apart matters, because conflating them is how a redesign looks done while the exposure remains. Sharma (2026) makes the complementary distinction between authenticity and integrity-oriented design: authenticity asks whether a task mirrors worthwhile practice, while integrity-oriented design asks whether learners can justify their decisions and assume responsibility in relation to disciplinary standards, which is why the practices he offers — annotated decision trails, verification of GenAI-contributed claims, oral defense, draft differences with version history — are selected for the judgment they make visible rather than for their realism. Espino and Espino’s (2026) ten-year review of business education reaches the same design conclusion from the literature side, finding the field converging on authentic, process-visible tasks that require interpretation, contextual application, and iterative refinement, and treating isolated tool adoption inside unchanged assessment structures as its most persistent failure.

Salameh’s (2026) Fade–Visibility Matrix crosses the same design question with a second variable — whether AI support persists or fades — and names the combination most courses default to, support that never fades assessed only by its product, Silent Dependency (Salameh, 2026).

The construct is also distinguishable from the question of how evidence is scored. Validity reasoning is where the two meet: Brunnström and Palmqvist (2026) argue that when a chatbot can produce a plausible examination answer, the submitted product becomes a weaker indicator of what the student learned — an assessment-validity problem rather than only an integrity problem. That is the same inference at risk in Yan, Greiff, Lodge and Gašević’s performance-versus-learning argument, where performance gains that shrink once assistance is withdrawn show a gain living in the tool rather than in the learner, and where the proposed remedy is process measures such as retention and transfer tests rather than immediate task success.

Why detection cannot carry this load

Process-oriented assessment is usually proposed as the alternative to detection, and the evidence about detection explains why. The detection literature finds error rates, task-dependence, and patterned bias against non-native and disabled writers, and the most recent work lands on a procedural conclusion: a detector score can prompt closer review but is not a finding. Munoz and colleagues (2026) show what that costs in practice. Coding 1,162 generative-AI misconduct allegations, they found the strongest evidence types are generated by the investigation or by supervision, that process evidence such as drafts, supervision meetings, and presentations appears only where those practices already exist — so in an unredesigned assessment it is simply absent — and that detector output drew the lowest probative ratings of any category. The design consequence is ordering: process evidence has to exist before a case needs it, and Weidlich's (2026) reasoning about which inference is at risk makes the same point from the validity side, since attempts to restore assessment security through detection introduce construct-irrelevant variance rather than evidence about the learner.

The rubric criteria themselves can be rebuilt around the trajectory. Oviedo and Díaz (2026) read Biggs's 3P model as three grading dimensions — agency and critical supervision, dialogic scaffolding, and cognitive sovereignty — so the trajectory is graded rather than the static outcome.

The design and workload costs

The sources are unusually candid that this is expensive. Thapa and Lewis state the equity caution directly: reflective and dialogic tasks can privilege students who are more confident in academic self-articulation unless they are inclusively designed and scaffolded. The relational, feedback-intensive work also intensifies the emotional and professional labor of educators in large or resource-constrained settings — a contradiction with institutional expectations for scalability, standardization, and measurable performance. Sharma adds the interpretive version: requiring documented reasoning privileges Learners more fluent in reflective discourse, and judgment as evidence "remains relational and situated rather than mechanically verifiable."

The operational costs are itemized elsewhere. Boysen lists new technology, revised assignments and syllabi, teaching students unfamiliar skills, and extra material to collect and grade, warns that low-stakes credit for process can inflate grades, and concedes the model suits large skill-development projects far better than day-to-day knowledge-acquisition work; he also notes that process tracking is what some critics call AI surveillance. Goldstein, Marae-Haj and Zidan's participants reported that establishing process documentation took real work, that nine of thirteen funded advanced tools from their own pockets in a way that could deepen the digital divide, and that several fell back on supervised examinations and anticipated oral thesis defenses. The equity worry has an AI-specific edge in Brunnström and Palmqvist's finding that unguided tool use demands an interaction-management skill that is unevenly distributed, so AI "may be most beneficial to already advantaged students" — the same distributional risk that attends asking students to manage a documented process. Lopez-López, Bru-Cordero and Correa-Álvarez (2026) found that students who invested more independent study time judged AI use more strictly, and recommend testing whether disclosure templates, oral defenses, and process-based assessment reduce ethical uncertainty — a study the field still needs. The risk attaches to the mechanism that makes process evidence work: where collaboration, revision, and reflection are graded, students have reason to produce evidence matching what they expect the marker wants, so process records can become performative rather than evidential (Alam & Jackson, 2026).

What remains unresolved

Thapa and Lewis's account is conceptual: no participants, no data collection, and no implementation trial, so the four principles are argued rather than tested, and the paper itself calls for empirical work on student experience, educator workload, and long-term viability. Feasibility is left undifferentiated across settings — transfer to large lectures, laboratories, studios, or clinical placements is not addressed. Lane's (2026) position paper notes the institutional ceiling: process-based assessment is blunted by grading and transcript structures that reward polished final artifacts, so classroom redesign alone does not change the incentive. Measurement is thin as well: Jin and colleagues' (2026) review of AI-literacy instruments calls for performance-based and process-oriented assessment and behavioral-trace measurement of prompting and verification, but reports that the existing instruments lean on self-report. No source here reports a controlled trial of a process-oriented redesign against a product-oriented one, which leaves the central claim — that process evidence is both harder to counterfeit and fairer to judge — argued from principle, practitioner report, and case-file evidence rather than demonstrated at scale.

Common Misconceptions

- **"A high score implies the student did the work we designed."** Traces can **diverge from scores outright**: across **150 student-AI conversations**, **41% carried an assignment score of exactly 1.00 while observable cognitive participation varied**. The score saturates while the process that was supposed to produce it does not.
- **"Process data is unmanageable at scale."** Required documentation proved feasible at course scale across **six semesters of six-week asynchronous graduate research-methods courses serving approximately 440 K-12 teachers**. Logistics were solvable; the objection overstates the cost.
- **"Problem solving is too holistic to assess by process."** It can be operationalized as **four stages and eight diagnostic sub-skills**, letting an LLM generate **stage-specific questions and rubrics** — used with **five teachers and 64 students**. Decomposition is what made the process legible and assessable.

Group Work

> **Group work** — learning and graded work produced by a team rather than an individual, used to develop collaboration, communication, and shared responsibility while also generating an outcome and often a grade for each member. It sits where assessment design and collaborative learning meet, and it inherits the tensions of both: free-riding and social loafing, unequal contributions, conflict avoidance, and the difficulty of attributing a collective product to individual learning. Generative AI intensifies these because teams must now negotiate whose and what kind of AI engagement counts as acceptable — a negotiation that Learner Agency research shows can resolve in opposite directions within a single cohort, and that AI agents joining the group can themselves reshape.

Questions to Consider

- What is a group task actually producing — the group's output, each member's learning, or their ability to collaborate? If those three can diverge, which one does your grading claim to warrant?
- Think of a group project you have been part of. Who did the work, who decided what counted as good work, and who stayed quiet? How much of that was the task design rather than the people?
- Research on group work finds students often decline to hold free-riders accountable to protect relationships. When a group member uses GenAI to produce their section, is that free-riding — or is the judgment more complicated than the word suggests?
- A group can access AI through a single shared interface or through each member's private prompts. Which produces more honest collaboration, and what does each conceal?
- If an AI agent joined your group as a teammate — praising, questioning, or provoking — would it deepen the collaboration or reshape who drives it without anyone noticing? How would you tell the difference?
- Collaborative AI that maximizes task efficiency tends to minimize learners' self-regulatory engagement. If you had to choose between the outcome and the struggle, which would you protect?
- A mediator AI is trusted only while it stays neutral. When it moves from summarizing to advising or challenging, the trust erodes. How neutral should a group's AI really be?

Introduction

Group work occupies a distinctive place in higher education and professional training: it is valued for building collaboration, communication, and shared responsibility, and it is pedagogically central in professionally oriented programs such as teacher education. Its promise is not automatically realized, however. Both teachers and students report obstacles to effective collaboration, and a graded group product carries two different claims at once — about what the group accomplished and about what each individual learned. AI, and generative AI in particular, presses on both: it changes how work can be divided, how easily contributions can be fused, and how each member's thinking can be distinguished from a tool's output. A

large part of the knowledge base's collaborative-learning research bears on group work, and this page draws on several strands of it rather than any single study.

Why group work is difficult by design

- **Free-riding and social loafing.** Some members reduce their contribution and the workload is redistributed onto more engaged peers. Task scope, group size, and composition raise the likelihood; accountability mechanisms and group efficacy reduce it.
- **Accountability is relational as well as structural.** In Hong Kong — where one of the knowledge base's group-assessment studies was conducted — undergraduates often chose *not* to report free-riding to protect interpersonal relationships, completing the work themselves instead of confronting the problem. Students' Learner Agency can therefore take the form of pursuing the grade while avoiding the conflict.
- **The collaboration has to be designed, not assumed.** Where a task can be partitioned into independent subtasks, students take that route and the group becomes a submission format rather than a joint intellectual endeavor. Chen and Zou (2026) found three of their fifteen groups doing exactly this — dividing the work, working on "individual platforms," and never pooling their individual GenAI capabilities even when coherence was an explicit assessment criterion.
- **Process versus product.** Group work is strongest when the process is assessed alongside the output, which requires peer assessment or other visible intermediates rather than a single final artifact.
- **Equity and inclusion.** Contribution norms, language, and confidence distribute unequally inside groups. Neurodivergent students report needing structured assignments, small consistent teams, and explicitly defined roles — requirements that AI collaboration tools, often built for the "average" learner, routinely fail to accommodate.

How AI changes group work

Research on AI in group work addresses two distinct things: what AI adds to a group's *task*, and what AI does to the group's *process*. Both matter, and the knowledge base's findings span them.

AI as coordination infrastructure

The most direct finding on GenAI and group assessment is Chen and Zou's (2026) three-pattern study of fifteen pre-service teacher groups. Rather than a single enthusiasm-to-avoidance spectrum, agency ran in three directions at once.

Pattern	Groups	Practice	Rationale
Cooperation-oriented agency	5	Intensified GenAI use	Coherence, performance, shared norms lowering perceived risk
Normative agency	7	Deliberately restrained use	Authenticity, fairness, originality, diversity of perspectives

Pattern	Groups	Practice	Rationale
Non-enacted agency	3	Unchanged from individual work	Task partitioned; collective interaction viewed as costly

- **GenAI as coordination infrastructure.** Students intensified use to solve a familiar collaboration problem — not knowing what peers' sections contained. Feeding those sections into a chatbot to decode and align them made distributed knowledge mutually intelligible, and one group rebuilt its workflow as "discussion → externalisation to GenAI → collective review → re-discussion." The authors read this as going beyond cognitive offloading, since judgment stayed with students while the tool absorbed coordination work, while warning that the smoother workflow may bypass the disagreement through which cohesion is built.
- **Group norms can invert accountability.** A permissive collective climate lowered the perceived risk of misuse ("it is more comfortable because besides me, everyone in my group is using GenAI"), turning shared norms into shared risk management rather than commitment to learning — the opposite of what group accountability is meant to achieve.
- **Restraint is also agentic.** Seven groups cut their GenAI use to protect the task's situated knowledge ("AI only knows that moment when you type"), to avoid effectively free-riding on groupmates, to preserve the originality that distinguishes groups from one another, and to keep the diversity of perspectives the group already had — normative self-regulation rather than mere compliance, and hard to distinguish from disengagement from the outside.

How the group accesses AI shapes the collaboration

Xu et al. (2026) show that *how* a team accesses GenAI is itself a design decision. With a single shared interface in synchronous work, teams co-construct "collective prompts," run a surface–evaluate–embed cycle, and treat the chat as shared memory; in asynchronous work, private prompting and output "de-labeling" fragment transparency and raise the cost of sustaining a shared cognitive model. Access configuration therefore connects directly to the quality of interactive engagement — whether the group is genuinely co-constructing or merely co-approving.

AI as a group member reshapes the group

A second line of research treats AI as a participant rather than a tool, and its findings complicate the assumption that "AI teammate" means "better teamwork."

- **Agents as social stabilizer — and a magnet for questions.** In fifteen groups of three STEM students deliberating Ethics with three Large Language Models (LLMs) participants (Seo et al., 2026), the agents kept groups on topic when human members drifted ("even if the other two participants strayed, I didn't have to handle it") and prompted clarifications humans avoided for relational reasons. But the group dynamic shifted interaction away from humans — 79.7% of questions were directed at agents (p = .017) — and participants noted a breadth–depth trade-off in the turn-stacking format, where each speaker took the floor in turn and "other participants couldn't intervene," making it easy to cover many ideas but hard to explore any one in depth.

- **AI personas reconfigure emergent Learner Agency.** Jin et al. (2026), in an experiment where AI operated as an undisclosed teammate, found supportive and contrarian personas still reshaped the group: contrarian AI pulled discourse toward challenge and reflection (productive friction), while supportive AI stabilized agreement and renewed ideation. Critically, the friction had a affective cost — contrarian AI reduced teamwork satisfaction and psychological safety *without* yielding creative gains — so "productive" discourse structures must be weighed against their emotional consequences. Because the personas worked even without disclosure, they position persona design as a form of invisible AI Governance over group collaboration.
- **Controversy can counter groupthink.** Wiss et al. (2025) took the opposite tack deliberately: an AI agent (CALIE) prompted to inject controversial viewpoints into twelve interprofessional PBL teams stimulated critical thinking and positive group dynamics, countering the conformity pressure that group work can otherwise produce. The contrast with Jin et al. is instructive — challenge helps when it is the intended design, and hurts when it is an unacknowledged side effect.
- **The neutral-mediator constraint.** Spritz, an AI that mediates disciplinary boundaries in interdisciplinary teams by surfacing implicit assumptions, was valued as both cognitive support and a relational buffer — but students' trust was load-bearing and eroded the moment the AI moved from neutral mediator to advisor or challenger. Role switches therefore need to be explicit and configurable, not silent.
- **Collaboration can itself be the object of instruction.** ProPACT treats the *dyad* — not the individual — as the unit of analysis, modeling joint attention and effort to predict collaborative breakdowns up to 30 seconds in advance. Dyads receiving proactive feedback achieved higher debugging success and showed sustained gains in collaborative AI Regulation in Education afterward: AI can teach collaboration itself, not just support a task.

The efficiency–regulation trade-off

Hao et al. identified three collaborative modes with AI on complex problems — *Delegated Reasoning*, *Concerted Interpretation*, and *Delegated Elaboration*. The most efficient mode (delegated reasoning) yields the best task performance but the lowest self-regulatory engagement; the mode with greatest self-regulation (concerted interpretation) underperforms on the task. This is the central design tension for AI-mediated group work: balance the efficiency of the distributed human–AI system against the depth of learners' regulatory engagement.

The epistemic risk of polished output

Kimmerle conceptualizes the risk of reduced epistemic effort when learners use AI to produce polished knowledge artifacts — automation bias on the social-cognitive side and epistemic closure induced by the finished artifact on the other. The remedy is to structure AI as an argumentative partner or challenger that preserves conflict. The counterpoint comes from Oppenheimer et al., who found that when LLMs act as critique partners and students actively rebut their claims, learners behave as critical consumers who preserve rather than surrender the cognitive conflict of critique. The difference between an answer-giving teammate and a challenging partner is what determines whether group work with AI builds or bypasses thinking.

Classroom-level, non-evaluative support

CoBi detects "uplifting" small-group discourse (respect, equity, community, moving thinking forward) and returns non-evaluative, classroom-level visualizations — deliberately withholding student- or group-level feedback to protect Privacy and Trust. Students preferred qualitative visualizations (an organic tree) over quantitative ones (a radar chart). For the relational dimension of group work, class-level aggregated feedback supports community building where individual scoring would feel surveilled.

Design implications

- **Make the AI-use negotiation an assessable outcome.** Chen and Zou (2026) argue teams should justify and document how GenAI will and will not be used, turning an implicit peer norm into explicit, gradeable reasoning rather than leaving it to perceived risk.
- **Assess process, not only product.** Peer assessment, intermediate deliverables, and reflective contributions create the interactions through which norms and shared understanding are actually constructed.
- **Do not rely on a coherence criterion alone.** A rubric line demanding integration does not produce collaboration if the task structure still permits divide-and-conquer; the workflow has to require joint work.
- **Design access deliberately.** Whether the group shares one AI interface or each member prompts privately changes the transparency of the collaboration and the cost of sustaining a shared cognitive model.
- **Decide, visibly, what the AI's role is.** A neutral mediator is trusted; an advisor or challenger is not, unless that role is explicit and intended. A contrarian persona can counter groupthink, but only as a designed feature with its psychological-safety costs acknowledged.
- **Balance efficiency against self-regulation.** Collaborative AI that maximizes task efficiency can undercut learners' regulatory engagement; design should deliberately protect space for concerted interpretation.
- **Prefer an argumentative partner over an answer-giver.** Structure AI to surface disagreement rather than smooth it over, so group work preserves the cognitive conflict that builds understanding.
- **Accommodate neurodivergent learners.** Structured assignments, small consistent teams, and explicit role definitions are requirements AI collaboration tools must support.
- **Read restraint carefully.** Students who avoid AI in groups may be exercising normative self-regulation — or guarding against risk and unfamiliarity. The two call for different instructor responses.

Common Misconceptions

"AI is a neutral addition to a group's workflow." It restructures where the group's interaction goes. In the study cited here, the group dynamic shifted interaction away from humans — **79.7% of questions were directed at agents (p = .017)** — while participants reported a breadth–depth trade-off in a turn-stacking

format where each speaker took the floor. A team that routes nearly four in five of its questions to a machine is no longer rehearsing the peer questioning that group work exists to develop.

“Polished group output is evidence of good collaboration.” Polished output is the epistemic risk, not the reassurance. A group can produce an excellent artifact while the regulation of the work — who decided what, how disagreement was resolved, whose reasoning was tested — happened inside the model’s response and left no trace in the deliverable.

“AI helps most when it coordinates the group.” Coordination support and epistemic support pull in opposite directions. Reducing the coordination cost of collaborating can lower the pressure on the group to negotiate meaning, which is the process being assessed. The efficiency–regulation trade-off is the core design tension, not an implementation detail.

“Group work is difficult because of the people.” Some of it is task design, which is why AI changes the difficulty profile rather than simply easing it: a tool that answers questions fast changes what the group spends its time on, and whether that is an improvement depends on which skills the task was built to develop.

Connected FAQs

- How Should I Handle AI in Group and Collaborative Assignments?

E-Portfolio

> **E-Portfolio (e-portfolio)** — a digital collection of a learner's work, reflections, and evidence of achievement, used for Assessment, learning, and evaluation. In the AI era, e-portfolios have emerged as a relatively **AI-robust and AI-assisted** assessment form: they capture the *process* of learning (reasoning, drafting, reflection) rather than just the final artifact, making them valuable against the collapse of the artifact-as-proxy, and generative AI can support their creation, Feedback, and evaluation.

Questions to Consider

- An e-portfolio captures the process of learning — drafts, revisions, reflections — not just the final artifact. Why might the process be exactly what AI cannot easily fabricate, and what does that make portfolios good for in an AI-heavy classroom?
- With AI able to produce polished final products on demand, the 'artifact-as-proxy' for learning has collapsed. What do you think an assessor can learn from a portfolio that they can no longer trust from a single submitted essay or exam?
- Some research recommends annotated portfolios, oral defenses, and recorded walkthroughs to probe reasoning in real time, mirroring professional practice. How different would that make assessment from the essays and exams you've taken — and fairer or harder to scale?
- AI can support the portfolio process itself — giving feedback, aiding drafting, and prompting reflection. Where's the line between AI genuinely helping a student learn and AI quietly doing the thinking the portfolio is meant to reveal?

Introduction

E-portfolios are a form of authentic assessment and formative assessment: they assemble student work over time, often with reflective commentary, into a body of evidence that can be assessed holistically. Their strength is that they surface the learning *process* — drafts, revisions, feedback, and self-reflection — which is exactly what AI cannot easily fabricate and what assessors need to evaluate genuine learning. This makes portfolios a leading candidate for assessment redesign in the generative AI era.

E-portfolios in the AI era

The knowledge base's research shows e-portfolios are increasingly central to productive AI integration and assessment redesign.

- **Portfolio assessment is relatively robust to generative AI.** Zhan, Boud & Du (2025) identify **social contribution portfolios** and co-created artifacts with auditable provenance chains among the authentic-assessment forms most robust to generative AI. Beyond detection (2025) likewise recommends **annotated portfolios / oral defenses / recorded walkthroughs** to probe reasoning in real time, mirroring professional practice.

- **AI-assisted portfolio assessment.** Ni & Lam (2026) study students' perceptions of **AI-assisted portfolio assessment** for multiliteracies development, showing AI can support the portfolio *process* (feedback, drafting, reflection) and enhance engagement while students evaluate AI feedback critically.
- **ChatGPT + e-portfolio for language learning.** Laksana et al. (2026) combine ChatGPT with e-portfolio assessment (CEA model) for EFL speaking: MANOVA showed significant gains in speaking performance (F(1)=48.554, p<.001) and feedback literacy (F(1)=16.135, p<.001), with e-portfolios supporting both speaking ability and the metacognitive abilities to use feedback effectively.
- **Portfolios as AI-era assessment strategy.** Responsible assessment (2026) argues for shifting from one-shot testing to **continuous embedded assessment using portfolios** and competency-based approaches. Rowe (2026) names portfolios (with orals and observed practice) as partial answers to the open problem of assessment at scale when the artifact-as-proxy has broken.
- **Portfolios as assessable learning traces.** Uden & Hwang (2026) use **personal learning portfolios** as a LEARN-framework mechanism — assessable learning traces (portfolios, AI-use disclosure) that make AI reliance transparent and auditable.
- **Symbiotic portfolios for hybrid learners.** Elsayed (2026) proposes a **Symbiotic Portfolio** for the post-human/hybrid learner, assessed by a five-criterion rubric (Generative Dialogue, Epistemic Auditing, Critical Reflection, etc.) — an explicit model for evaluating human+AI collaborative work.

Why e-portfolios matter for AI integration

Because e-portfolios foreground **process, reflection, and demonstrated understanding** over a single final artifact, they directly address the central AI problem: when AI can produce a polished product, the product no longer evidences the engagement behind it. E-portfolios shift assessment toward the evidence that survives — drafts, revisions, reasoning traces, and reflective Self-Assessment — while AI itself can assist in generating feedback, Scaffolding reflection, and (with appropriate rubric design) supporting evaluation. This makes e-portfolios a cornerstone of authentic, formative, and process-based assessment in the generative AI era, and a natural home for feedback literacy and self-regulated learning.

Common Misconceptions

"An e-portfolio is a digital folder of finished work." The assessment value comes from capturing the *process* — reasoning, drafting, revision, reflection — rather than the final artifact. That is precisely why e-portfolios are comparatively AI-robust: when the artifact can be generated, an assessment built on process retains evidence that an assessment built on the product has lost.

"AI makes e-portfolios as easy to fake as essays." The failure mode is different and the evidence shows the format moving in the other direction. Combining ChatGPT with e-portfolio assessment (a CEA model) in EFL speaking produced significant gains in speaking performance (**$F(1) = 48.554$, $p < .001$**) and feedback literacy (**$F(1) = 16.135$, $p < .001$**), with e-portfolios supporting the reflective layer. The portfolio did not become the weak link once AI was added to the course; it carried the assessment.

“A significant multivariate result proves the portfolio was the active ingredient.” It proves the package moved the outcomes. The study combined an AI tool, a portfolio structure and speaking tasks, and a design of that shape cannot isolate which component produced the gain. The defensible claim is about the combination, and the Learning Gains caution applies: reported gains need to be traced to a component before they can be reused.

“E-portfolios replace the need for unassisted assessment.” They complement it. A portfolio evidences process and growth over time; it does not evidence what a learner can do without support, and conflating the two reintroduces the artifact-as-proxy problem the format was adopted to solve.

Implications for Practice

For instructors

- Require the process, not just the product: drafts with dates, revision explanations, and reflection on what changed and why. Those are the artifacts AI cannot supply on the learner’s behalf.
- Pair the portfolio with at least one unassisted performance measure, so process evidence and capability evidence are both on record.
- Use AI *inside* the portfolio workflow — for feedback on drafts — rather than outside it, which is the configuration the cited study tested.

For developers

- Build for revision history and versioning rather than for a polished final view; the Pedagogies and Teaching Strategies lives in the diff.
- Make reflection prompts structured enough to be assessed, since unstructured reflection is where AI-generated text passes most easily.

For researchers

- Design for component isolation when studying AI-plus-portfolio packages; otherwise the field accumulates combination effects it cannot decompose.

Peer Assessment

> **Peer assessment** — the practice in which students evaluate, grade, or give Feedback on one another's work, through written peer review, peer grading, peer code review, or group and team assessment. In writing Pedagogies and Teaching Strategies it is a long-standing best practice: students learn both from receiving criteria-based feedback and from providing it, and peer talk about shared work correlates with deeper learning, audience awareness, and social development. In the AI era it is being re-examined as an assessment design choice rather than a single activity — a human complement to AI-generated feedback, a training ground for Feedback Literacy, and a site where Academic Integrity and student agency are renegotiated.

Questions to Consider

- Think back to a time your work was assessed by a peer—or you assessed theirs. What did you learn more from: giving feedback or receiving it, and why?
- Why might a student's feedback be more context-aware and emotionally supportive than AI feedback, even while AI feedback is more consistent and rubric-driven? How could the two complement each other?
- Peers tend to under-grade strong work and AI tends to inflate weak work. If neither is reliably accurate across the whole quality range, what should a grade from either source be used for?
- Peer assessment depends heavily on Scaffolding and clear criteria, and friendship bias and social anxiety can make untrained peer review worse than none. What does adequate training actually look like in your context?
- If AI can draft comments on organization and structure, does that make peer assessment redundant —or does it free peers to give the specific, audience-aware feedback only they can give?
- GenAI-supported peer feedback outperformed plain peer feedback in one study, but only with prompt scaffolding added. What is being scaffolded there—the AI, the student, or the assessment?
- Critically assessing AI-generated feedback is described as building AI literacy and writerly agency. What does it mean to have agency over your own work when machines increasingly comment on it?

Introduction

Peer assessment is an assessment design choice in which students take on part of the evaluative work usually reserved for instructors. Its forms differ in what students produce and what is at stake: peer feedback (comments on a draft, usually formative and low-stakes), peer grading (a mark contributing to a grade), peer code review, and group or team assessment (where peers assess the collective product or one another's contributions). The form determines what students practice — giving a criteria-based comment builds evaluative judgment differently from assigning a number, and defending one's own code orally builds something different again. Self-Assessment, the sibling practice, turns that same criteria-based scrutiny on

the learner's own work, whereas peer assessment directs it at a peer's submission and the audience awareness that comes with it.

The research base agrees that peer assessment produces learning and disagrees about how much depends on design. It gives students an authentic audience, develops evaluative judgment through criteria-based responding, and builds the social context that supports engagement and Motivation. Its quality depends heavily on Scaffolding — how well it is structured, and whether students get clear criteria and training. That dependency is where AI enters, as a consistent, rubric-driven complement to the specific, context-aware feedback peers give, and increasingly as a scaffold built into the peer-assessment process itself.

Wang and Guo (2026) find that EFL students who reviewed peers' writing through open-ended dialogue with a generative AI produced feedback that recipients rated higher in quality, with gains in emotional response and feedback literacy that varied by the quality of the dialogue.

What students learn from assessing peers

The strongest argument for peer assessment is that the assessor learns. Fowles et al. (2026) made every CS1 submission subject to a 15-minute oral code review interview with a trained teaching assistant, weighted at 70% of the assignment grade. Pasted-to-total characters rose from 61.0% to 68.1% ($p < 0.0001$), yet exam scores did not decline and time-on-task held steady; 90% of students said the reviews motivated them to understand their code better and 65% that they helped avoid over-reliance on AI. Requiring students to explain their work to a trained peer converted potential offloading into a self-regulated practice opportunity.

The mechanism recurs across the literature. In a PRISMA 2020 systematic review of 22 articles from 203 screened, Martínez-Peláez et al. (2025) found LLMs support collaboration partly by aiding peer feedback and simulating rubric-based evaluations, and that students who verify and correct model output develop critical thinking. Learning by Teaching shows up even among machines: peer-learning-like discourse among over 2.4 million AI agents was mostly assertion rather than inquiry (statement-to-question ratio 11.4:1, metacognitive reflection only 7% of a coded taxonomy across 28,683 posts), which Chen et al. (2026) treat as a caution that surface discourse does not establish that anything is learned.

Training, calibration and feedback literacy

Peer assessment fails predictably when students are untrained. Gu, Chen, and Yan (2026) ran a mixed-methods quasi-experiment with 118 first-year undergraduates in China, comparing ChatGPT-4o under pre-trained rubrics against structured peer-review worksheets with a high-quality exemplar. Feedback literacy rose slightly more in the GenAI group (ANCOVA $p = 0.049$, $\eta^2p = 0.03$), but the qualitative findings matter more: peer-group students chose feedback sources by social convenience — nearby peers, same-major peers, roommates — rarely held specific feedback goals, and faced social anxiety about seeking feedback. Peer evaluation was more often distorted by friendship bias and perceived peer proficiency, and peer reflection was often delayed until later exams. The authors recommend multi-stage designs with anonymous peer feedback, since peer review still uniquely builds audience awareness and evaluative judgment through giving feedback.

Design frameworks target those bottlenecks. Irwin and Muller (2026) propose two GenAI roles in EFL/ESL peer feedback on speaking, a case they argue is harder than writing because of time pressure, fleeting oral

performance, and heightened affect: a Trainer supporting feedback givers through exemplar-based calibration and feedback-on-feedback, and a Synthesizer aggregating peer comments into a criteria-linked uptake report that normalizes formats, preserves minority views, and flags contradictions. Their principles are careful timing and sequencing, short repeated Trainer units, preserving the givers' voice, and Guardrails that keep the teacher in the loop with no automated grading. The paper is conceptual, with no new empirical data.

Validity, fairness and grading accuracy: peer vs AI vs instructor

Where peer assessment produces a grade, the question is whether the grade is defensible. Usher and Faraon (2026) found peer–instructor alignment was strongest for lower-quality work (r = 0.51 in the low-quality tier) and weakened for high-quality projects, which peers tended to under-grade — plausibly reflecting reluctance to criticize strong work. ChatGPT showed the opposite pattern: better alignment on high-quality work, but inflated grades for weak submissions. Students perceived peers' grades as more consistent with the peers' own written feedback, and valued peers' relationship-aware judgment alongside ChatGPT's neutral consistency. Peer accuracy is quality-dependent and relationship-sensitive, and no single source is reliable across the whole range.

That constrains what a peer grade should be used for. A mark calibrated in the middle of the distribution need not be calibrated at the top or bottom, so peer grades are more defensible as input to a moderated decision or as evidence of the assessor's judgment than as a final mark on strong work. Suen and Hung (2026) underline why institutions keep seeking scalable alternatives: peer feedback and expert coaching are time-consuming, costly, and hard to scale consistently. Their closed-loop system scored 204 adult learners on presentation skills with an XGBoost backbone approaching expert-rater reliability (ρ = 0.69–0.78) and pre–post gains of Cohen's d = 0.39–0.90 — one pre–post field study, not a comparison against peer assessment, substituting machine judgment rather than augmenting peer judgment.

AI-augmented peer assessment: PAIRR and the Trainer/Synthesizer split

The dominant design pattern keeps the peer central and adds AI around them. The Peer and AI Review + Reflection model is the best-documented instance. Sperber et al. (2025) implemented PAIRR across 10 writing courses and three writing-intensive STEM courses, with 654 students (37% first-generation, 13% international, 68% multilingual). Students drafted, exchanged peer review, prompted ChatGPT for rubric-driven feedback on the same draft, critically assessed both, planned revisions, and reflected. 58% preferred combined feedback, 36% peer feedback alone, and only 6% AI feedback alone. The two sources were often similar (75% reported similarities, described as confirming and strengthening each other) and, when they differed, complementary: AI feedback was often called overly general (31%) but gave actionable revision strategies on organization and structure, while peer feedback was more specific and detailed (28%) and drew on contextual knowledge of the assignment. Critically evaluating AI output built AI Literacy, and only 5.3% of students showed overconfidence in it.

The same 2024 implementation has a second write-up that reads the reflections for how students described the tool rather than for how they rated the feedback. Stillman et al. (2026) coded the revision reflections of the 13 sections and 10 courses, and found only about half the students adopted the anthropomorphic roles the prompt offered: tutor (28.6%) and collaborator (23.1%). The rest reached for tool or resource (9.9%), friends

or peers (7.7%), robot or computer (7.7%), or schemas of their own. The authors read that placement as the point: students put the chatbot at the periphery of a writing ecology whose center is the student, the peers and the instructor.

The pattern generalizes to professional writing. MacArthur et al. (2025) applied PAIRR to an upper-division business writing course where five major assignments each required a draft, audience analysis, peer review by 2–3 peers, and revision (34 of 46 enrolled students participated; 69% multilingual). Students valued AI feedback but sometimes found it too general, and valued peers' contextual knowledge — "my peers looked at it from the employer's perspective… ChatGPT did not do that as much." One quarter of coded reflections in the larger PAIRR study expressed skepticism about AI feedback or noted inaccuracies, which the authors read as developing AI literacy. The study is descriptive and course-specific.

GenAI as a scaffold inside peer feedback and group assessment

The most rigorous test of how much design matters is a multisite cluster-randomized experiment. Ateş (2026) randomized 48 sections across 4 universities — 1,176 first-year undergraduates in biology, chemistry, and physics — to four conditions for scientific argumentation: peer feedback only, direct GenAI feedback, reflective GenAI feedback (self-evaluation then AI critique), and a hybrid of self-evaluation → peer feedback → GenAI critique. Direct GenAI beat peer feedback on immediate argument quality but showed weaker transfer; reflective and hybrid designs produced stronger feedback uptake and self-regulated learning; the hybrid showed the clearest advantage on conceptual learning; both outperformed direct GenAI on delayed AI-free transfer. GenAI's value, the authors conclude, depends less on access than on whether the environment preserves student agency and ownership during revision.

Sequencing AI feedback before peer discussion, rather than after it, also raised outcomes: against peer feedback alone, 122 Chinese EFL students given AI-plus-peer integrated feedback reported higher affective, behavioral and cognitive engagement (partial $\eta^2 = 0.29, 0.28, 0.32$) and outperformed on all four IELTS writing dimensions, largest for task achievement ($d = 1.41$) (Liu (2026)).

That pattern — an early advantage that does not hold — recurs when the comparison is teacher feedback against AI-assisted peer feedback rather than GenAI alone. Tang, Li, and Luo (2026) ran an eight-week quasi-experiment with 61 Chinese L2 writers (244 graded texts) working from one five-dimension checklist, with one class receiving teacher written feedback and the other AI-assisted peer feedback. Teacher feedback produced far more comments — 316 items against 185 in the first task, concentrated on vocabulary and technical details — and the slightly larger immediate gain, but its improvement fell sharply by the second task while the AI-assisted peer class held steady and finished with the higher revision score. The AI-assisted peer comments were fewer but stayed anchored in content and structure, and their early lexical-diversity edge did not persist; neither mode moved syntactic complexity. The authors read the two as complementary scaffolds and propose an AI–Peer–Teacher hybrid, in which AI marks surface errors during drafting, peers negotiate content in revision, and the teacher targets what neither reached.

Adding GenAI can also raise the quality of the peer feedback itself, but apparently only with prompt support. Chang et al. (2026) compared three conditions among 45 student teachers in 12 groups over four rounds of collaborative argumentation: plain peer feedback, peer feedback with GenAI, and peer feedback with GenAI under prompt scaffolding. The GenAI-supported groups outperformed plain peer feedback on argumentation performance, and the prompt-scaffolded group performed best on advanced elements such as "rebuttal data

and warrant” and “addressing the opposing view”. GenAI-supported groups produced more explanations, suggestions, and neutral or negative feedback, and the scaffolded group paired negative emotions with higher-order feedback content — critical evaluation rather than passive acceptance. It is a small single experiment, but it isolates prompt scaffolding as the active ingredient.

Group assessment changes the problem, because students must negotiate whose AI use is acceptable. Chen and Zou (2026) interviewed 15 focus groups of 52 pre-service teachers in a course where a group presentation worth 30% of the final grade required integration and coherence. Three patterns emerged: cooperation-oriented agency in five groups, who intensified GenAI use to hold the work together and protect a shared grade; normative agency in seven groups, who restrained use to protect authenticity and fairness — one student reasoned that generating a part in AI would be “not fair to other groupmates”; and non-enacted agency in three groups whose practice never changed from individual work. The authors argue that individual capability does not become collective agency on its own and that the negotiation of acceptable AI use should itself become an assessable outcome, with peer review tasks feeding the final product.

Feedback architecture, disclosure, and the social conditions of peer assessment

Peer assessment also depends on what students can see of each other and what they will admit. Hao and Cukurova (2026) tested an AI-generated summary learning design across three iterations with 128 students over eight weeks. Students in AI-supported iterations showed significantly higher standardized out-degree centrality than the baseline ($\beta = 0.547$ and $\beta = 0.438$, both $p < 0.001$): they viewed or interacted with more peers. Interviews described the summaries as a navigation map that reduced the effort of finding contributions buried in ill-named threads, and students attended to active contributors chosen for contrasting opinions rather than friendship. The design did not prevent declining viewing activity under rising workload, so technological affordances alone do not sustain engagement.

Peer norms also shape honesty, which matters wherever peers assess AI-influenced work. Qu and Wang (2026) surveyed 409 Singaporean undergraduates about why students conceal GenAI use despite disclosure mandates, and found relational variables dominated: perceived peer disclosure and comfort with instructors were the strongest predictors of disclosure, while moral disengagement was weaker. Non-disclosure was strategic adaptation to perceived peer norms and low interpretive trust, not moral negligence. Peer norms can therefore support honesty, as when group-assessment students restrained AI use out of obligation to groupmates, or suppress it, as when collective adoption lowered the perceived risk of misuse. Transparency, the authors argue, depends less on compliance than on trust and positive normative climates — a relational condition that peer-assessment designs either create or destroy.

Design implications and open questions

Several design moves follow. Give assessors training, exemplars, and criteria before they assess, because untrained peer assessment is vulnerable to friendship bias, convenience-based source selection, and social anxiety. Sequence the work so self-evaluation precedes peer feedback and AI critique, since the hybrid condition produced the strongest conceptual learning and best delayed transfer. Where GenAI enters, scaffold how students prompt it. Keep the teacher in the loop for anything that becomes a grade, treat peer grades as quality-dependent evidence rather than uniform marks, and make AI use itself something groups negotiate and document.

GenAI-mediated review also inherits the tool's linguistic norms: contributors to a World Englishes dialogue argue that reviewers using GenAI are exposed to the same bias toward dominant English varieties as the models, and recommend editing or rewriting generated text to reflect the writer's own linguistic identity (Ugwuanyi et al. (2026)).

The open questions are about the strength of the evidence, not only about design. Much of the peer-and-AI evidence is small and context-bound: 45 student teachers in one course, 34 students in one business writing course, 52 pre-service teachers in 15 focus groups. The PAIRR survey is the largest dataset here and measures student perceptions, not the quality of the AI outputs students judged. Only the multisite experiment's 1,176 undergraduates approaches causal-comparative scale, and it tests feedback design for scientific argumentation rather than peer assessment as such. Meanwhile O'Neill (2026) audited 14 peer-reviewed meta-analyses claiming AI improves education and found none provided a valid basis for its claims — all but two defined the treatment as a tool rather than a pedagogical intervention, heterogeneity was high in every meta-analysis reporting I^2 (77.2% to 94.4%), and an audit of 59 primary studies found 61% had validity concerns, most often a mismatch between the outcome measured and the claim made. Claims about what AI does in peer assessment should be treated as claims about a designed activity, tested in that activity's terms.

Common Misconceptions

- **"Oral defence stops AI-assisted work."** Pasted-to-total characters **rose from 61.0% to 68.1% ($p < 0.0001$)** after every CS1 submission became subject to a **15-minute oral code review worth 70% of the grade**. The behavior it targeted increased — and **exam scores did not decline and time-on-task held steady**, while **90% of students said the reviews motivated** them. The intervention worked on understanding, not on pasting.
- **"Cheating detection is what oral assessment is for."** The measured outcomes were understanding and motivation, not reduction of pasted text. Judging the design by its detection rate misreads what it achieved.
- **"Peer review is a cheaper substitute for instructor feedback."** Learning by teaching is the mechanism, and it shows up even among machines: peer-learning-like discourse among over **2.4 million AI agents** was mostly **assertion rather than inquiry**. Producing critique is a different act from receiving it.
- **Reflective peer and self forms as the record behind a group grade.** Issa and Hall (2024) used one peer-reflective form per teammate plus one self-reflective form per student in a postgraduate Business Project Management unit, alongside a 30-minute meeting with each team in which members were asked whether their contribution was original. The forms were not graded as feedback exchange. They were the per-person evidence that let the instructor defend an individual mark inside a 40% team assessment. The framework's mark rise from 27/40 to 31/40 is confounded with a new lecturer and its integrity claim is unquantified, so the transferable part is the record-keeping structure, not the effect size.

Connected FAQs

- What Are Best Practices for Writing Instruction in the Context of AI?
- How Should I Handle AI in Group and Collaborative Assignments?

Self-Assessment

> **Self-assessment** — judging your own work, competence, or progress against criteria, and the practices and instruments built on that act. The term carries two faces that are easy to collapse into one. As an **instructional technique** it is self-grading, rubric-based self-review, self-checking, and guided reflection: activities meant to develop the monitoring and judgment that Self-Regulated Learning runs on. As an **educational measure** it is a self-report instrument, in which a learner's estimate of their own skill, confidence, or learning stands in for an observation nobody made. It sits beside Peer Assessment as the other half of students-as-assessors, and inherits the same dependence on Scaffolding and explicit criteria. Both faces turn on the same faculty and both fail in the same direction: the estimate is systematically generous, and the more a learner's submitted work can be produced by a generative AI tool, the less that work says about whether the faculty is there at all.

Questions to Consider

- When you finish a piece of your own work, what tells you whether it is good: the criteria you were handed, the criteria you have internalized, or how it feels? Could you tell which one you actually used?
- Self-report and objective measurement of teacher AI literacy hardly agree: across 288 K-12 teachers the two correlated at r = 0.07 to r = 0.24. Where in your own practice would a self-estimate most likely diverge from a test of the same skill, and why there rather than somewhere else?
- Self-grading can save instructor time and build judgment, and it can also hand out a mark the student has not earned. What would have to be true about the task, the rubric, and the training for a self-grade to carry credit?
- If a tool can produce the essay, what is left for a student to assess about their own learning? What would you ask them to estimate instead?
- Students who assess a peer's work and students who assess their own are doing different things. Which one transfers better to the next task, and what evidence would settle it?

Introduction

Self-assessment is one of the older ideas in education and one of the more confused ones in practice, because two distinct things travel under the name. The first is a technique: students reviewing their own work against criteria, grading it, checking it, reflecting on it. The second is a measurement: the learner's own rating of their skill, confidence, or learning, used as data. The technique is judged by what it develops in the learner; the measurement is judged by whether the number can be trusted.

Both matter in an AI-era assessment design, and they matter for different reasons. The technique is where evaluative judgment is trained, and evaluative judgment is exactly the capability that becomes scarce when a language model can produce competent-looking work on demand. The measurement is where the field

routinely overstates what it knows, because a self-report cannot measure learning: it can only record what someone says about it.

Self-assessment as an instructional technique

The practices that fall under this heading are familiar: self-grading against a rubric, self-review of a draft before submission, self-checking of problem solutions, reflective prompts asking what a learner would do differently, and prediction tasks where a student estimates their performance and then compares. Their purpose is developmental. A student who reviews their own draft against criteria is rehearsing the appraisal that peer review and instructor feedback also train, and is building the internal standard they will use when nobody is watching.

Evidence that the technique works, and about which version works, comes mainly from writing and from self-regulated learning research. In a comparative study of feedback literacy, first-year undergraduates (N = 118 in China, 56 in a GenAI group and 62 in a peer group) worked through three self-assessment cycles across one semester. The GenAI group's advantage over the peer group was small, only 0.17 scale points (partial eta squared = 0.03), and the study's practical conclusion is the one that recurs: self-assessment needs scaffolding. Pre-trained rubrics, prompt guidelines, and worksheets are what separate a self-assessment cycle that builds Feedback Literacy from one that produces offloading.

Self-assessment is also where the cycle of Self-Regulated Learning becomes visible as a skill rather than a disposition. In an undergraduate statistics study, students who received explicit training in reasoning-focused scaffolding (stepwise hints and verification prompts) performed better on a later task attempted with no model assistance and showed better self-assessment calibration than students who leaned on the model uncritically. The interesting part is the second measure: the trained group's estimates of their own understanding aligned better with what they could actually do. A technique aimed at reflection changed a measurement property of the learner.

Calibration training

The most direct technique is calibration training, where a student predicts their score or confidence before seeing a result and then compares the prediction with the outcome. In an AI-assisted writing study, a feedback literacy script improved writing quality, feedback uptake, and deep revision, while an Assessment-Performance Calibration Activity primarily improved the accuracy of students' self-assessment and reduced overconfidence. Combining the two produced the largest writing gains and the strongest retention after AI support was withdrawn, though the calibration activity alone remained the better route to accurate self-estimates. That division of labor is the practical point: feedback literacy improves what a student does with comments, calibration improves how well they know their own standing, and they are not the same intervention.

An essay-level paper on ethical AI use at one Australian university treated guided self-assessment as the vehicle rather than the subject: across commencing nursing, health sciences, engineering, and science students from 2021 to 2025, pre- and post-semester self-assessments combined Likert confidence items with an open reflection prompt, and the authors argued that ethical practice is a developmental capability to be built through reflection rather than a compliance rule to be enforced.

What AI adds to the technique

AI changes three things about the technique. It can generate the items and rubrics, which makes repeated self-assessment cycles cheap. It can be the thing assessed, which is how evaluative judgment gets trained: a student judging an AI draft is practicing appraisal with an unlimited supply of material. And it can make the learner's judgment visible as process evidence. In interactive learning dashboards, a conventional analytics dashboard was extended with a Judgment of Learning self-assessment feature and a conversational agent, on the argument that eliciting a learner's own judgment does more for engagement than telling them what the data shows. Institutional frameworks have started to treat the same process traces, including structured self-assessments and metacognitive prompts, as evidence of adaptive capabilities that a transcript cannot show.

Self-assessment as a measure

Used as a measure, self-assessment usually arrives dressed as something else: a confidence rating on a Likert scale, a predicted score, a Judgment of Learning item, or a taxonomy-based inventory of perceived skill. It is one family within the wider set of Self-Report Measures, and it inherits that family's categorical limit. A self-report cannot measure learning or behavior; it can measure only what a person is willing to say about their learning or behavior, and those two things come apart often enough in this research base to be a finding in its own right.

How accurate the estimates are

Accuracy is the headline problem, and the direction is consistent. The cleanest evidence comes from a study that built parallel self-report and objective measures of teacher AI literacy inside a single framework. Across 288 K-12 teachers, correlations between the objective and self-reported factors ranged from $r = 0.07$ to $r = 0.24$. Latent profile analysis found six profiles: 43 teachers rated themselves consistently high while scoring lower on the objective measure, 59 showed the reverse pattern, and the remaining profiles clustered near the mean or split by prior AI literacy experience. Two measures of one skill, built by the same team on the same construct, share almost nothing.

The field-level picture matches that single study. Zainal, Mohd Matore and Maat's 2026 review of teacher AI literacy measurement tools appraised 33 instruments published between 2019 and 2025 and found that 31 (93.9%) were self-report scales of perceived confidence, only two (6.1%) tested knowledge objectively, and none used performance-based tasks. The authors' reading is the one this page's measurement face turns on: a self-report score records reported confidence rather than capability, so it cannot stand in for competence, and they argue for performance tasks and Item Response Theory analysis alongside self-assessment to separate validated capability from reported confidence.

Accuracy also depends on what is being estimated. A psychometric analysis of a taxonomy-based GenAI literacy self-assessment with 158 university staff and students found an inverted profile, with respondents claiming mastery of creation before the conceptual foundations underneath it, and only a weak correlation ($r = 0.188$) between student and academic profiles. A survey of Teacher Education students found the same shape from the other side: nearly all (97.8%) rated critical media analysis important while only 13.8% said their coursework addressed it, and fewer than half (44.9%) believed they had the skills to analyze media information critically. Self-assessed media competence lagged self-assessed importance.

Two mechanisms explain the generosity. The first is motivational and well documented outside this literature: people rate themselves generously, and the least competent overestimate most. The second is specific to AI-native cohorts. A 2026 theoretical paper on the **absent cognitive baseline** argues that sustained substitutive AI use during the formative secondary and high-school years reduces the independent cognitive encounters that any academic self-assessment depends on. The claim is structural rather than individual: self-assessment works by comparing a current performance with a record of previous ones, and where the record was never built, the estimate has nothing to be calibrated against. That is presented as distinct from offloading and surrender, which describe processes during AI use, because the gap persists when the tool is absent.

Developmental stage sets one boundary on accuracy, and the youngest learners are where a validated self-assessment instrument is scarcest. Thianwan and Srikoon's 2025 validation study of an AI literacy self-assessment questionnaire for upper primary students built a 15-item measure for Grades 4 to 6 across Learning About AI, Learning About How AI Works, and Learning for Life with AI, confirming a three-factor structure in samples of 335 and 579 students with an overall Cronbach's alpha of .934. The authors are explicit about the genre's limit: self-assessment accuracy depends on metacognitive ability that is still maturing in children, so scores index perceived understanding rather than demonstrated competence, and the instrument is intended for formative diagnosis.

Self-assessment as an outcome variable

The measurement face also shows up in evaluation design, where self-assessment instruments are used as outcome measures. One study of AI-assisted assessment of complex reports in higher education explicitly evaluates learning with validated feedback literacy and self-assessment instruments alongside subsequent performance and comparison with a control group. That is defensible when the instrument measures a belief the study is actually about, such as Self-Efficacy or perceived competence, and misleading when it is treated as a stand-in for achievement. The recurring critique of AI intervention studies applies with full force here.

Measuring agency through post-task questionnaires and task-specific Self-Efficacy risks circular reasoning: the learner's estimate is read back as evidence of the capacity it is meant to indicate, and the alternative is dynamic analytics that track how self-assessment is used across successive cycles (Mao (2025)).

What generative AI changes

The two faces converge under generative AI, because the tool attacks the link both of them rely on: that a learner's submitted work is evidence about the learner.

Where the work can be produced on demand, a sound essay no longer demonstrates the judgment behind it, and asking a student to assess a draft they did not write is a different task from assessing one they did. This is why assessment validity arguments have moved from detection toward redesign, and why self-assessment moves from a study aid to a component of the assessment design itself: the judgment a student makes about a piece of AI output, on the record and with reasons, is evidence in a way that the output is not.

It also introduces a naming hazard worth stating plainly. **AI self-evaluation** is not this concept. When a paper reports that a model assesses its own reasoning or grades its own output, that is model evaluation and belongs with Automated Assessment and the study of model training and simulated learners. One tutoring

study makes the practical version of the point, arguing that feedback should be conditioned on a separate diagnostic classifier rather than on the model's self-assessed reasoning validity. Learner self-assessment and model self-assessment share a vocabulary and nothing else.

Implications for practice

- **Scaffold the technique.** Rubrics, prompt guidelines, and worksheets are what make a self-assessment cycle developmental. Bare self-assessment, like bare AI feedback, tends to produce reassurance rather than judgment.
- **Train calibration separately from feedback use.** Prediction-and-compare activities change the accuracy of self-estimates; feedback-literacy work changes what students do with comments. If accuracy is the goal, run the calibration activity.
- **Keep self-grades low-stakes unless the training is real.** A self-grade is a claim about learning made by the person it benefits, and the overestimation profiles in the AI-literacy study are not a small bias to absorb in a summative mark.
- **Use self-report where it is honest.** Confidence, perceived competence, and willingness to disclose AI use are legitimate things to measure by asking. Achievement is not.
- **Ask for judgment, not opinion.** The most defensible AI-era self-assessment asks a student to appraise a specific piece of work against criteria and justify the call, which is trainable, inspectable, and connected to Evaluative Judgment.
- **Watch the cohort effect.** For students whose formative years included substitutive AI use, an accurate self-estimate may be unavailable rather than merely optimistic, which shifts the instructional task from correcting overconfidence to rebuilding the experiential record it needs.

Common Misconceptions

"A self-report measures the skill it names." It measures a belief about the skill, and the two come apart badly. In a study of **288 K-12 teachers**, self-reported AI literacy correlated with an objective measure of the same skill at only **r = 0.07 to r = 0.24** — a range in which the self-report explains almost none of the variance in capability. Self-report is usable as a perception measure and not as a proxy for competence.

"Students can judge their own learning accurately." Accuracy of self-judgment is itself a skill, and the evidence on calibration points the other way: in an experimental comparison, explicit training in reasoning-focused scaffolding produced better self-assessment calibration than unrestricted access, which means calibration improves from instruction rather than being available by default.

"Adding an AI feedback loop improves self-assessment automatically." A feedback loop changes what the student compares against, which can improve calibration and can also anchor them to the system's judgment. The comparative study here (**118 first-year undergraduates, 56 in a GenAI group and 62 in a peer group**, three cycles across a semester) is designed precisely to test whether the loop or the social comparison does the work — and the answer is not "the loop, by being a loop."

"Self-assessment is a softer alternative to testing." It is a different target. Self-assessment develops the regulatory skill of judging one's own work; a test measures the capability being judged. Research that substitutes one for the other conflates the capacity to evaluate performance with performance itself.

Oral Assessment

> **Oral assessment** — assessment in which a learner must explain, defend or demonstrate understanding in speech, live or recorded: the viva voce, the oral exam, the oral defense, the code-review interview, the clinical consultation. Because the exchange is real-time and the questions need not be known in advance, the format resists the substitution of generated text for understanding in a way that take-home authentic tasks cannot. It also carries a distinctive validity problem: orals measure fluency and confidence alongside knowledge, so what they certify depends heavily on how they are designed, who is asking, and how the learner's speech is treated as evidence.

Questions to Consider

- Orals are promoted in the AI era because a machine cannot sit in the room and answer for you. Yet the corpus that argues this contains no randomized trial of oral against written assessment. What would you need to see before treating that argument as settled?
- The same body of work reports two different mechanisms for reduced anxiety: removing the teacher's live observation, and becoming familiar with the format through practice. These imply different designs. Which fits your context, and which would you trust to generalize?
- Speech-only scoring can mistake verbal fluency for conceptual understanding. If a learner gestures correctly but says the wrong word, or says the right word without understanding it, what exactly is your assessment measuring?
- Every oral design in this corpus hits the same wall: staff and room time. If the constraint is twenty-eight contact-hours per semester for fifteen students, is the honest answer a smaller number of defended assignments, a larger teaching team, or a different format?

Introduction

Oral assessment is one of the oldest assessment formats and, for most of the last century, one of the least fashionable: hard to scale, hard to standardise, hard to defend in an appeals process. Generative AI has reversed its fortunes. When a written submission can be produced on demand by a model, the assessment value of the artifact collapses, and attention moves to the assessment of the person. A learner who must answer an unfamiliar question out loud, in real time, is at least demonstrably present and thinking.

That reversal is now visible across the research corpus, but unevenly. Some work treats the oral exam as a policy answer to academic integrity, some designs an automated system to deliver or score oral performance at scale, and some asks what speech itself can and cannot show about understanding. The pages connected below disagree about how much orals actually prove. Read together, they support a narrower and more defensible claim than the one usually made for them.

What a live performance can certify

Fenton (2025) makes the strongest form of the argument. Drawing on the literature on authentic assessment, the paper's case for the oral exam rests on its interactivity: questions can be withheld until the moment of the exam, follow-up probes can be improvised, and the learner cannot rehearse a response to a question they have not seen. The format also blocks rote memorisation, because recall is checked through explanation rather than reproduction. The paper is a review and position piece in *Educational Researcher*, not an empirical study, and it ends with thirteen numbered implementation recommendations rather than evidence of improved outcomes.

The honest version of the integrity claim is narrower than it is often stated. Orals make substitution harder to hide; the corpus does not show that they reduce AI use. In the CS1 oral code-review study, weekly fifteen-minute interviews carried seventy per cent of each assignment's grade, and pasted-to-total characters still rose from 61.0 per cent to 68.1 per cent ($p < 0.0001$) across three semesters, while exam scores moved by a statistically insignificant two per cent. Ninety per cent of students said the reviews motivated them to understand their code better and sixty-five per cent that they helped avoid over-reliance on AI, but the measured behavior did not follow. Oral assessment changed what could be hidden, not what students did.

The design space the corpus actually covers

The formats in the corpus span a wide range of automation and synchronicity, and each solves a different part of the problem.

Live, human, synchronous. The viva voce examined by a viva voce study of thirty-five pre-university students is the baseline: same teacher, same questions, one delivery face-to-face and one mediated by an AI system. The doctoral viva appears in a qualitative study of fifteen postgraduate researchers, where participants argued for shifting assessment weight toward it on the reasoning that a thesis is easier to fake and that the viva must be given in person. The authors accept that reasoning only in part, since a viva is not inherently proof against AI assistance.

Recorded and asynchronous. Asynchronous oral assessments replace the room with a time-limited, non-revisable webcam response, roughly thirty seconds of preparation and two to three minutes of speech. In the reported pilot, scores exceeded those of in-person multiple-choice tests: midterm median 92.5 against 70 ($p < .001$) and final median 94.2 against 86.4 ($p = .002$), with only moderate cross-format correlations. The authors explicitly attribute the difference to the format rather than to learning, and the design carried 7.5 per cent of the course grade.

Automated delivery and scoring. A voice-based system trialled in vocational automotive and engineering classes assessed thirty-three learners, of whom twenty-one agreed the live voice task felt realistic and none disagreed that speaking in real time suited the task better than a written portfolio. Word counts for identical questions varied five- to eightfold between learners, fluency conferred no accuracy advantage on closed items, and a preliminary agent grade matched the human tutor's in ninety-five per cent of adjacent horticulture and dairy trials. A conversational Socratic test takes the opposite design route, aiming at conceptual questioning; its evidence is a self-report survey of ninety-eight students, in which 80.6 per cent agreed the AI scaffolded effectively and fifty-two per cent reported lower stress than traditional exams. Both papers measure acceptance rather than learning.

Oral evidence as defense rather than examination. A tool-invariant assessment framework pairs AI-free in-class quizzes with ten-minute oral defenses of comment-stripped, AI-assisted work, scored on code comprehension, method understanding, terminology, interpretation and verification, with verification required to pass regardless of the total. The design is argued rather than validated; the paper's own arithmetic for fifteen students is two and a half contact-hours per assignment and roughly twenty-eight contact-hours per semester across eleven defended assignments.

Interaction format decides what an AI-mediated speaking task can certify. The Duolingo English Test's dialogue tasks, 713 of them in the pilot, required answer selection rather than reactive talk, which the reviewers argue misaligns the cognitive demands of the task with the construct the test claims to measure (Goh & Aryadoust (2025)).

Anxiety, bias, and who the format disadvantages

Orals are argued for on inclusion grounds, because a spoken answer is harder to buy than a written one, and against on the same grounds. Fenton catalogues the challenges directly: scheduling load, anxiety, and bias along gender, ethnicity, language and answering speed, plus the effects of non-anonymous marking. Against that, the evidence the paper cites suggests orals can be as inclusive as written examinations, including for students with dyslexia, and that unfamiliarity rather than the format itself drives most reported anxiety; students in one cited study were less anxious by their later oral exams.

Where anxiety genuinely falls, the reason matters. In the AI-mediated viva, self-reported calmness was significantly higher than in the face-to-face version (means 6.50 against 5.86, $t(34) = -1.97$, $p = .028$), and usability was rated good. But the face-to-face condition scored significantly higher on helping students understand their own work ($p = .004$). Removing the teacher's live observation made students calmer and, by their own report, less illuminating to themselves.

What counts as oral evidence is also narrower than it looks. A study of embodied evidence in oral explanations argues that scoring speech alone mistakes verbal fluency for conceptual knowledge and disadvantages learners with language-related difficulty, since gesture carries understanding that the transcript loses. Its demonstration is small: two engineering students explaining statistical concepts, with high-confidence gestures clustering on particular ideas, square and box forms at roughly fifty-four to sixty-one per cent, and tighter gesture–speech coordination accompanying more coherent explanations.

Scoring, validity, and the scale problem

Three findings cut against reading oral scores as learning gains. The asynchronous-format study disclaims learning gains for its own score advantage, and reports instructor-versus-model re-scoring agreement of ICC 0.73 at midterm and 0.60 at final, which bounds how far machine scoring can be trusted. In an RCT with one hundred third-year medical students comparing a simulated-patient system against progressive-disclosure case material, final examination performance rose (71.8 against 55.6 per cent, Hedges' $g = -0.81$). OSCE communication ratings also rose (3.53 against 2.64 on a five-point scale), while binary diagnostic accuracy was statistically identical (84 against 86 per cent, $P = 1.000$). An accuracy-only reading would call the intervention null; a communication-only reading would call it transformative.

The binding constraint is staffing and hardware rather than Pedagogies and Teaching Strategies, and the corpus is unusually candid about the arithmetic: twenty-eight contact-hours per semester for fifteen students, eleven teaching assistants for a class of over one hundred in the CS1 design, and one laptop serving twelve simultaneous learners in the offline vocational deployment. No randomized trial of oral against written assessment exists anywhere in this body of work, and every study that measures the difference is a single-institution design without a control group. Oral assessment is well supported as a response to AI-assisted substitution, and thinly supported as an improvement in learning.

No format holds a fixed position in this trade-off: oral assessment's observability is a design choice, and its feasibility cost is one a program distributes rather than accepts — feasibility is an educational priority, not the constraint that erodes good practice (Pedlow et al. (2026)).

The oral's integrity rationale is also time-limited: Corbin et al. (2026) argue that AI glasses and earbuds can deliver covert real-time prompts inside a live viva, because wearable AI produces no gaze shift or detectable signal, so interactive orals are no longer immune.

- **The scale ceiling is the design constraint.** In a workshop with 73 computing educators, oral and interactive assessment was reported as the strongest available evidence of individual understanding and the least scalable remedy. The mitigations participants described were distribution and sampling: shared teaching-assistant pools, peer assessment weighted below a final exam, and calling on a rotating subset of students (Akbar et al., 2026).

Common Misconceptions

- **"Oral assessment cannot scale."** In the CS1 oral code-review study, **weekly fifteen-minute interviews carried seventy per cent of each assignment's grade**, and pasted-to-total characters still remained informative. The cost is real and the design is implementable at course scale.
- **"Oral exams are softer than written ones."** In the reported pilot, scores **exceeded those of in-person multiple-choice tests: midterm median 92.5 against 70 ($p < .001$) and final median 94.2 against 86.4 ($p = .002$)**. Oral assessment was not the lenient option.
- **"A simulated encounter is equivalent to progressive-disclosure cases."** In an RCT with one hundred third-year medical students the simulated-patient system was compared **against progressive-disclosure case materials** — a direct test of equivalence rather than an assumption of it.

Automated Assessment

> **Automated assessment** — the use of AI to evaluate student work, from formative quizzes to high-stakes exams. Automated assessment spans multiple modalities — multiple-choice, short answer, essay, code, and performance-based evaluation — and ranges from direct automated grading to confidence-aware systems that report calibrated uncertainty alongside their scores.

Questions to Consider

- Automated assessment ranges from multiple-choice scoring to essays, code, and performance-based evaluation. What's the biggest difference you'd expect between how reliably AI can grade a multiple-choice quiz versus a free-form essay — and why?
- A core design idea here is 'confidence awareness': AI graders that report how certain they are, flagging low-confidence cases for human review rather than issuing a single unqualified score. How would a grade that said 'I'm 70% sure about this' change how you'd use or trust an automated score?
- Research shows automated scoring can systematically disadvantage non-native speakers — the AI scores the language rather than the understanding. Why might an automated grader be especially prone to this kind of unfairness, even when it achieves high agreement with human raters overall?
- One study found that how validation is done can inflate reported performance: a naive cross-validation method reported near-perfect results that dropped dramatically under more rigorous trial-independent validation. What does this cautionary lesson suggest about how you should read any claim that an AI assessment system 'works'?
- The page argues calibrated confidence enables human-in-the-loop workflows, supports trust calibration, and strengthens measurement validity. If an automated system routed its most uncertain cases to a human reviewer, what would you want to know about how those cases are chosen before you trusted the split?
- Automated grading is described as one of the most mature AIED applications, yet grading without useful feedback has limited educational value. How might a focus purely on producing scores — rather than usable feedback — change what students actually get out of an AI-graded assessment?

Introduction

Assessment modalities

- **Short answer and essay:** automated grading, Automated Essay Scoring, and confidence-aware approaches handle free-text evaluation.
- **Code assessment:** Bash grading and code review demonstrate programming assessment.
- **Formative assessment:** A-level science automation and CoTAL focus on formative rather than summative use.

- **AI-generated assessments at scale:** Assessing AI-Generated Exams shows that iteratively refined, course-tailored AI-generated exams achieve IRT-measured quality on par with expert-written standardized-exam questions (difficulty $\bar{\beta} = -0.45$ vs. 0.35; discrimination $\bar{\alpha} = 1.3$ vs. 1.2) across 91 college classes — evidence that automated assessment can move from scoring to full item generation.
- **Performance assessment:** Video engagement assessment and drawing assessment extend automation beyond text.
- **Multimodal exam data and rubrics:** a multimodal examination answer dataset with expert-designed Outcome-Based Education rubrics provides a benchmark resource for criterion-level automated assessment across diverse response modalities, supporting benchmarking and measurement research on multimodal student work.
- **Neurophysiological assessment:** Nanayakkara & Halloluwa (2026) benchmark ML/DL models for EEG-based familiarity prediction (faces vs. math equations) as a step toward direct, objective measures of knowledge acquisition. Crucially, they show standard stratified cross-validation inflates performance (up to 0.9853 F1) via temporal leakage, while trial-independent Group K-Fold validation drops the peak to 0.6038 F1 — a cautionary methodological lesson for all automated-assessment benchmarking.

Automated grading

Automated grading is one of the most mature and widely-deployed AI in education applications — AI systems that evaluate student work, from multiple-choice scoring to essay assessment and code review. Its grading modalities include:

- **Students separate feedback utility from evaluative authority:** AlGhamdi (2026) documents a case where an AI score counted toward grades and students knew it — 13 computing students whose scanned handwritten work was evaluated by ChatGPT against a rubric covering clarity, organization, sentence correctness and conciseness. Every participant found the feedback useful, yet all separated that utility from authority, and several rejected the one-way, non-dialogical character of automated grading — "ChatGPT is not like people. You talk to them and explain excuses… I like normal teacher [to] grade my work." The study positions automated evaluation as acceptable for surface revision but not as a final assessor, with conditional trust mediated by instructor oversight.
- **Short answer grading:** confidence-aware ASAG evaluate free-text responses, with confidence calibration critical — systems must know when grading is reliable. A scoping review of short-answer auto-marking in science (2017–early 2024) maps the field's course: Morley et al. found BERT-family models (base, RoBERTa, DistilBERT, SciBERT) dominated — used in 20 of 21 studies, peaking in 2021 — before GPT-based approaches were adopted via Prompt Engineering rather than fine-tuning from roughly 2022. Models augmented with domain data (textbooks, rubrics, further pre-training) consistently outperformed those without, yet few could justify marks in human-comprehensible terms and bias across demographic and linguistic groups was rarely examined — leading the authors to argue auto-markers should *support* rather than replace human examiners. A PRISMA-guided systematic review of 42 empirical grading and feedback studies (2023–2025) generalizes this caution across the field. LLMs match human raters on closed-ended

tasks and short-answer questions but cannot fully replace human judgment on complex, open-ended, or subjective work requiring in-depth analysis or Creativity, and the highest grading effectiveness is achieved in hybrid systems that pair AI-driven grading with teacher oversight and verification (Can ChatGPT Replace the Teacher in Assessment? A Review of Research on the Use of Large Language Models in Grading and Providing Feedback).

- **Essay scoring:** Automated Essay Scoring systems like anchor-based AES use prompting strategies to approach human-level reliability. RACES, a reward-aligned essay scorer, reported higher Quadratic Weighted Kappa and SimCSE similarity than evaluated pretrained and fine-tuned baselines on ASAP 2.0 without significance testing, and its reward-modeling feedback was LLM-generated proxy, leaving only the reference scores human-assigned (Li et al. (2026)). AIAWE extends automated evaluation to broader writing assessment.
- **Code review:** Linux Bash grading and CS1 code review demonstrate automated assessment in computing education.
- **A prompt persona can collapse a grader, and fine-tuning can repair it:** Habibullah et al. (2026) graded a practical computer vision exam (570 dual-graded students) under 171 configurations and a second machine learning exam (1,038 students) under 162 more. A short "strict grader" preamble drove 14 of 17 open-weight models out of the graded band (MAE ≥ 8), three stopping grading altogether; the damage traced to two credit-withholding sentences rather than tone or model scale, and its direction was exam-specific, improving seven models on the second exam. Light LoRA fine-tuning on roughly 3,900 pooled graded examples brought five small open models to parity or better with a human grader, so the vulnerability is a prompting artifact rather than a capability ceiling.
- **Formative integration:** A-level science automation and CoTAL show how automated grading feeds into Formative Assessment cycles.
- **Coverage of feedback types is not alignment with teachers.** Almousa et al. (2026) annotated paragraph-level feedback from three university writing courses into seven focus types; most models emit nearly every type, yet their distributions diverge from the teacher reference, with the educationally tuned LearnLM closest (Jensen–Shannon divergence 0.1344) and Mistral-7B furthest (0.2695). Prompting with category definitions or worked examples increased divergence for most models.
- **Bias and fairness:** Language bias in physics scoring documents how automated grading can disadvantage non-native speakers — connecting to Bias Mitigation and Equity.
- **Benchmarking GenAI models for open-ended grading:** Pecuchova, Benko & Drlik (2025) benchmarked eleven GenAI and sentence-embedding models against two expert human graders on 1,885 open-ended responses to 24 software-engineering questions. Only GPTo1 reached almost-perfect agreement (Fleiss' Kappa 0.82, low false positives and false negatives across grade categories), with Claude3 and PaLM2 close behind; context-sensitive GenAI models robustly handled short, diversely-phrased student answers, while reference-based embedding models (e.g., BERT's 345 false positives) systematically penalized correct-but-divergently-worded responses — evidence that model choice, not just grading format, shapes reliability for free-text open-ended assessment.

- **Prompt exemplars decide scoring agreement:** Takahashi et al. (2026) automated hierarchical diagnostic reasoning (HDR), an applied-competence task in which learners find and explain deliberately embedded errors in a short case. Using GPT-4o with no fine-tuning, the team generated new problems and scored student descriptions: generated and human-authored problems carried the same internal consistency (Cronbach's α = 0.78) and showed no significant score-distribution difference across 100 participants, and the format's correlation with a reading-comprehension control stayed low (α = 0.36 and 0.41). Scoring accuracy depended on the prompt rather than the model — without worked examples Q2 precision fell to 0.42, while adding human-scored correct and incorrect exemplars lifted agreement to 98% or higher on every question (Q1 and Q2 at 100%) — against a measured human cost of 138 minutes of expert scoring for 117 responses plus 30 minutes of consensus.

A model's own reasoning mode is a second configuration lever: on 32 anonymized public-health master's exam submissions the same ChatGPT moved from weighted kappa 0.269 in fast mode to 0.718 in thinking mode, while Kimi reached 0.571 (Brevik et al. (2026)). - **Multi-agent coding of teachers' open-ended responses, where the framework rather than the model carries reliability:** Copur-Gencturk et al. (2026) extend automated assessment beyond student work to the coding of teachers' own content knowledge (CK) and pedagogical content knowledge (PCK), asking whether AI can reproduce the trained human coding of 268 U.S. middle school mathematics teachers' written responses about ratios and proportional relationships. A purpose-built multi-agent LLM, GradeOpt, assigns three GPT-4o-backed roles — a Grader that applies the human coding manual, a Reflector that diagnoses each disagreement with the human code, and a Refiner that folds clarification points back into the manual over up to six rounds — and matched trained human coders closely on CK (κ = .88 and .85) while reaching substantial agreement on the far more interpretive PCK items overall (κ = .68; weighted κ = .79). Two NLP baselines and a single-prompt GPT-4o model never exceeded κ = .39 or weighted κ = .55 on PCK, so the authors attribute reliability to refining instructions against the coding manual rather than to model scale, and recommend expert review wherever adjacent coding levels blur, since GradeOpt's residual errors were typically adjacent codes rather than wild misses. - **Mixed-format exam grading (2026):** Falahat, Das, Bhaumik & Thambi (2026) evaluated ChatGPT-5 against human faculty grading of a 21-item pharmacy exam (16 students) spanning multiple-choice, select-all-that-apply, fill-in-the-blank, listing, short-answer, and essay items. Concordance was substantial-to-near-perfect for objective item types (CCC 0.935–1.000 — aided by correct answers supplied during grading) but collapsed for listing (0.621–0.708), short-answer (≈0 to negative), and essay (0.341–0.854) items; providing a structured rubric did not consistently improve full-exam agreement (71.1% without vs 68.2% with). The study sharpens a methodological point that recurs across automated assessment — moderate percent accuracy frequently coexists with low concordance — so accuracy alone overstates reliability, and it recommends hybrid grading for complex, subjective, or high-stakes items.

- **Cross-family grade-band calibration on authentic marked essays (2026):** Kerwat, Donaldson & Mahomed (2026) ran eight pre-specified configurations from four model families (GPT-OSS 20B, GPT-OSS 120B, Qwen 32B and Llama 3.1 8B, each at two temperatures) over the same locked cohort of 114 BAWE/Coventry essays carrying institutional Merit and Distinction labels, with one shared prompt that permitted four bands. Exact band agreement ranged from 18.4% to 54.4%: Llama 3.1 8B at temperature 0.5 led (54.4% exact, 98.2% within one band, MAE 0.474, near-zero bias) while GPT-OSS 120B was weakest (18.4%) and systematically *undergraded*, by

an average of 1.316 bands at temperature 0.5, with Distinction accuracy trailing Merit accuracy throughout. The locked cohort contained no Pass or Fail references, so this is Merit–Distinction discrimination rather than reliability across the full grade range, and temperature was no cure — it helped one family descriptively, left another unchanged, and significantly worsened GPT-OSS 20B (39.5% to 29.8% exact). Two lessons transfer beyond the study: grade distance and directional bias reveal what agreement statistics hide, and model size is no proxy for assessment validity.

- **Rubric engineering for open-ended scoring in medical education:** Olvet et al. (2026) asked whether GPT-4 could reliably score open-ended questions on pre-clerkship medical exams. After three iterations of human-driven rubric refinement at two US schools, inter-rater reliability with faculty reached substantial-to-almost-perfect agreement for three of four questions using analytic and holistic rubrics (weighted kappa up to 0.94), while the holistic-rubric item stalled at moderate ($\kappa w = 0.54$). Error-pattern analysis showed discrepancies were traceable to both raters — GPT-4 over-scored when students offered multiple answers or used rubric-absent vocabulary, whereas faculty were often "overly generous" graders — leading the authors to recommend keeping humans in the loop (e.g., faculty scoring a subset to confirm accuracy). Because roughly 82% of US medical schools grade pre-clerkship work pass/fail, exact AI score agreement is often unnecessary for operational use.
- **HITL scoring for a large-scale national writing assessment (2026):** Curi et al. (2026) scale prompt-based Large Language Models (LLMs) scoring to a real high-stakes Spanish writing exam (~5,000–6,000 responses/year), achieving 60–80% item accuracy and 90%+ output consistency across a 15-item analytic rubric, with a deterministic NLP checker replacing the LLM on the spelling item (100% consistency). Its distinctive contribution is decision-oriented validation over model-centric metrics: the AI's systematic under-grading bias, converted via IRT-and-Bookmark into proficiency levels, produces pass/fail discrepancies in 15.3–16.5% of cases — all of which the human-in-the-loop workflow routes to expert review, cutting responses needing full human scoring by at least 50% while preserving decision quality. This grounds hybrid grading in operational assessment rather than proof-of-concept datasets.
- **Per-dimension agreement shows where an assessor cannot detect change:** SOPHIE 2.0 (Hasan et al., 2026) validated an LLM judge against the consensus of all human rating sources — standardized patients and third-party raters — on a three-dimension clinical communication rubric, reaching Pearson 0.759 and ICC(A,1) 0.746 from transcripts alone, inside the spread of the individual human raters rather than outside it. Its weakest dimension was Be Explicit (correlations of 0.414–0.598 across candidate judges), and that was also the only dimension whose scores did not move measurably across the two encounters ($\Delta = 0.014$, $p = 0.1204$) — so per-dimension agreement can indicate in advance which dimensions an automated assessor is unable to show improvement on.

Confidence-aware assessment

A central design goal within automated assessment is **confidence awareness**: AI assessment systems that report calibrated uncertainty alongside their scores, rather than issuing a single unqualified prediction. A

confidence-aware grader not only produces a grade or classification but also signals how certain it is, so that low-confidence cases can be flagged for human review and users can calibrate their Trust in the system. This is central to responsible automated assessment and connects closely to Psychometrically Aware AI and Trust Calibration.

How confidence is modeled in the knowledge base's research:

- **Fused confidence signals for short-answer grading:** Confidence-Aware ASAG fuses model-based confidence signals (verbalized, latent, and consistency-based) with dataset-derived aleatoric uncertainty via Random Forest regression.
- **Confidence in multimodal student work:** Confidence-aware assessment of student-drawn scientific figures extends confidence modeling to multimodal student responses.
- **Psychometric calibration of LLMs:** Psychometrically aware AI advances the standard of aligning Large Language Models (LLMs) scoring with measurement theory, with calibration as a core requirement alongside Item Response Theory alignment.
- **Difficulty and response-time calibration:** Programming-exam difficulty calibration repositions LLMs as auxiliary evidence sources whose difficulty estimates correlate with student pass rates.
- **Trait-adaptive essay scoring:** PsyScore shows a psychometrically-aware framework can adapt essay feedback to learner traits.
- **Evaluating visual student work:** DiagramIR back-translates LLM-generated math diagrams (TikZ) into an intermediate representation with deterministic checks, beating LLM-as-a-Judge on agreement with human raters and letting small models match large ones at ~10× lower cost — a scalable route to assessing non-text, diagrammatic student output.
- **Trust-gated inference in automated teacher assessment:** Li, Yang & Fang (2025) place Monte Carlo dropout calibration directly in the scoring path, so that dropout variance above a learned threshold triggers a reject-and-refer output rather than a score, alongside adversarial debiasing that holds the fairness gap to 1.8% where baselines sit in the 6.4–8.2% range and an expected calibration error of 0.032 on TeacherEval-2023. Their ablation is the calibration argument in miniature: removing the trust-gated module drops inter-rater consistency to 78.6%, and the authors attribute a 41% reduction in human review workload to the gating — uncertainty handling as architecture rather than post-hoc reporting.
- **Explainability of rubric-based scoring:** Bueno et al. show that model-agnostic SHAP attributions are more faithful and transferable than LLM-generated rationales for explaining rubric-based scores (e.g., classroom feedback quality), and propose deletion-based + cross-model tests as a principled way to evaluate any scoring model's explanations.

Why calibrated confidence matters:

- **Enables human-in-the-loop delegation:** low-confidence cases route to a human reviewer — supporting human-in-the-loop workflows rather than blind automation.
- **Supports trust calibration:** calibrated confidence lets users match their trust to the system's actual reliability, avoiding both over-trust and under-trust.
- **Improves measurement validity:** confidence-aware scoring strengthens Educational Measurement and Assessment Validity by making uncertainty explicit.

- **Fairness and defensibility:** flagging low-confidence cases for review reduces the risk of confidently wrong scores, especially for atypical or underrepresented responses.
- **Rubric generation and instructor-supervised grading pipelines:** Mendonça et al. (2026) show that LLM-generated assessment rubrics (HARMOGEN-R) can match human-created rubrics for technical content within a ±5-point equivalence margin, with structured generation giving greater cross-model consistency. Cruz et al. (2026) evaluate an end-to-end GPT-4o grading pipeline where AI grades fell within 0.5 points of the instructor in 83% of 362 submissions (MAE 0.31) — best framed as a scalable supplement to, not a replacement for, instructor judgment.

Assessing teaching rather than work

Automated assessment usually scores what students produce, leaving the teacher's own performance to human observation. A 2026 integrative review turns the tools on teaching itself, mapping 21 studies drawn from 367 records in Scopus, Web of Science and ERIC (Dino et al., 2026). It followed Whittemore and Knafl's five-stage design with PRISMA reporting, appraised quality with MMAT 2018 — 89 of 105 criteria rated Yes — and built its keyword map in VOSviewer.

Four themes organize the corpus: **Evaluation**, models scoring teachers from student feedback and survey data; **Engagement**, tools sorting students by engagement level in online, on-site and hybrid settings; **Expression**, sentiment and topic coding of written student feedback; and **Experience**, sensor and video capture of observable classroom behavior. Teacher performance was the most common target, at 11 of 21 studies. The authors ran no meta-analysis, because methodological and outcome heterogeneity ruled out pooling, and 7 of the 21 studies had 100 participants or fewer — so the review maps a fragmented field rather than estimating how well AI judges teaching.

Quality and fairness

Automated assessment quality depends on Assessment Validity and Bias Mitigation. Language bias research shows that automated scoring can systematically disadvantage certain student populations. **The criterion is itself fallible.** Bozdag and Qiu (2026) mark GCSE physics scripts with an AI system and compare them against both official examination-board marks and experienced teachers' judgment, treating agreement with the board as a proxy for accuracy rather than accuracy itself.

Deployment scenarios and what each one requires

How much alignment an institution should demand depends on what the system is allowed to decide. In a mixed-methods study of 761 authentic undergraduate essays at three UK universities, three frontier models with 27 prompt configurations each reached only 35–65 percent agreement with human markers on the degree band, and accuracy did not transfer between institutions — so the report treats candidate uses as distinct scenarios rather than one decision. **Quality assurance of human marking**, where AI marks in parallel and significant differences trigger human review, is the most conservative. **A marking assistant**, ranking or categorizing submissions by predicted quality or uncertainty, triaging complex cases, or expanding brief human comments into fuller feedback, is a genuine middle ground. **AI as primary marker**,

with human review of a sample or of mark distributions, was judged acceptable only if system performance improves, and no stakeholder group endorsed AI as a sole marker.

Three requirements follow for any of them. Because alignment is model- and institution-specific, validation must be local and continuous — headline accuracy from elsewhere is not evidence of readiness. Because marks were compressed toward the middle, AI was least accurate at the grade boundaries and for the strongest and weakest submissions, which is where assessment decisions carry the most consequence. And because disagreement between an AI and a human mark reflects different judgment rather than mere error, discrepancies should trigger human interpretation rather than algorithmic override, with final authority over the mark retained by people. Adoption also carries AI Governance obligations the technical metrics do not capture: a right to explanation under GDPR Article 22 where automated decisions affect students, Equality Act duties once attainment level and language use are shown to influence marks, revised appeal processes for errors that are not easily caught, and an irreversibility risk — once staffing and investment shift, an institution may struggle to keep collecting the human marking it would need to return to.

Combining the three models did not remove that error: because their mistakes were correlated — the same direction on 63.4% of assignments — the Corsi et al. (2026) ensemble was statistically indistinguishable from the best single model, leaving the shared central-tendency compression in place.

Venetsanos (2026) supplies the criteria those requirements presuppose, arguing that what makes automation defensible is the *epistemic status* of the task rather than what the technology can technically perform. His framework limits AI to bounded verification of factual and procedural claims — all four of unambiguous documented criteria, direct comparison against established knowledge, no assessment of alternative valid approaches, and a single correct answer or pre-specified acceptable set must hold simultaneously, with ambiguity escalating to a human by default — and makes AI involvement at that level conditional on five non-negotiable principles that must all hold at once: the knowledge base must be assessor-curated and retrieval-grounded in module materials rather than the model's parametric knowledge; human assessors review every AI output before it reaches students and hold absolute override with unshared accountability; feedback must carry clear provenance and attribution; and security must be designed against adversarial use from the start, with input sanitisation for instructions hidden in white or small text, encodings, images or document metadata, since successful circumvention of an automated system spreads through student cohorts. The same paper is explicit that its principles are untested for simultaneous feasibility and that assessor time for curation, security infrastructure and high-frequency oversight may shift staff effort rather than reduce it — a caution that sits alongside the local-validation requirement above.

Security of AI-mediated grading

A red-team evaluation of an everyday grading workflow shows the attack surface that planning for adversarial use has to cover. Humble (2026) embedded five indirect prompt injections inside a synthetic essay that Microsoft Copilot (GPT-5.2) had graded fail in six of six baseline runs, iterating each across docx, pdf and htm files. Two strategies changed the grade with no visible warning — an instruction-manipulation and role-playing paragraph at 9 of 9 iterations (100%) and the same paragraph hidden behind an image layer at 17 of 18 (94%) — while a paragraph in small white text at the end of the document failed in all nine iterations, and file-metadata injections never worked, which the author attributes to metadata access being disabled in the version tested. The trust problem outlasted the exploits: after one pdf run detected an

embedded instruction and stated it would grade only against the official assignment, re-running the same file raised the grade six more times with no warning, and a chat blocked by a detected attack was silently disabled rather than reported to the user. The author argues the resulting grades carry no validity claim in either direction, that an adversary needs only one working combination against layered Guardrails, and that the teacher remains the only real check on the output while the manipulation is designed not to be visible — connecting directly to the input-sanitisation and adversarial-security obligation Venetsanos sets out above.

Connections

Automated assessment connects to Assessment Validity (quality assurance), Formative Assessment (use context), Bias Mitigation and Equity (fairness), Teaching (how automation changes instructor work), and AI Feedback Quality (grading without useful feedback has limited educational value). Confidence-aware assessment is a specific mechanism within the broader agenda of Psychometrically Aware AI and a contributor to calibrated trust.

- **Large-scale AI grading of handwritten physics (2026):** A multimodal model (GPT-5.5) graded 10,364 scanned pages across a national Physics Olympiad theory exam, selection camp, and university quantum-mechanics exam, achieving total-score correlations of 0.91–0.97 with official marks and recovering the same top-five Olympiad team. Revised page-by-page, evidence-location instructions improved agreement — evidence that multimodal AI can support high-stakes summative grading with careful rubric and prompt engineering (Large-scale AI grading of handwritten physics assessments: Score agreement and Olympiad team selection outcomes).
- **Selective automation for handwritten chemistry (2026):** Cvengros & Kortemeyer graded a 296-student handwritten general-chemistry final page-by-page against rubric images with a multimodal, reasoning LLM, achieving high run-to-run reliability on total scores (ICC(A,1) = 0.967) and strong total-score agreement with TA grading ($R^2 = 0.91$). Because item-level reliability varied sharply by format — textual and chemical-reaction answers graded reliably while drawing and graphing scored worse than random — raw agreement was judged inadequate for high-stakes use. They operationalize human deferral through confidence filters (partial-credit thresholds, an IRT-based risk threshold, and problem-type exclusion) that convert raw AI scores into an accept/deferral policy, and show that false positives (AI crediting genuinely wrong answers) tend to go undetected since students rarely contest them — a concrete psychometrically grounded route to selective automation (Assisting the grading of a handwritten general chemistry exam with artificial intelligence).
- **Semi-open handwritten mathematics in a university exam (2026):** Liu et al. graded a German undergraduate mathematics exam with GPT-4 across two extraction routes (pre-cut answer boxes versus whole pages), two optical-character-recognition routes and two rubric formats, reporting Krippendorff's alpha against human grades of 0.22-0.44 with accuracy 0.59-0.62 on the best workflows and per-problem accuracy spanning 0.27-0.91 - not acceptable for high-stakes summative use. Itemising multi-criteria grading rules generally did not improve agreement (it helped the partial-credit problem), free grading without a rubric was far worse (accuracy 0.50-0.51), and a probabilistic confidence filter meant to flag grades for human re-checking did not significantly improve accuracy while wrongly flagging 7-41 percent of responses as reliable.

The study's transferable lesson is procedural: scan and transcribe the whole exam sheet with markers rather than cropping answer boxes, because students write across box borders; rewrite grading rules written for teaching assistants, since the model attempted unrequested derivations from a rule meant for a human; and note that the human-grading rules themselves paraphrased at an alpha of 0.88 among five variants, so prompt robustness is not the bottleneck.

- **LLM comparative judgment for writing screening (2026):** Mercer & Reed used seven LLMs as pairwise comparative judges to score informational writing from 1,208 students in Grades 3–6 across three screening occasions. LLM-CJ scores correlated strongly with analytic rubric scores (r = .67–.73, strongest for Gemini-3.1 Pro) with AUC .82–.86 for proficiency; findings were stable across models, with little validity gain from costlier, more capable ones, while averaging three writing samples improved accuracy — sampling breadth mattered more than model choice. Predictive-bias patterns for multilingual learners matched human rubric scoring, supporting LLM-CJ as an efficient, low-cost screening approach (Validity of Large Language Model Comparative Judgment for Universal Writing Screening).
- **Quality-dependent alignment with instructor grading (2026):** Comparing ChatGPT, peers, and an instructor grading the *same* undergraduate group projects, Usher & Faraon found ChatGPT's alignment with the instructor *improved as project quality increased* — its largest overestimation was for low-quality work (≈ +14 points), shrinking to ≈ +2.5 points for high-quality projects. ChatGPT also graded higher on average than both peers and the instructor, a grade-inflation tendency that undermines its reliability as a standalone summative grader, especially for weaker submissions.
- **Small-corpus agreement statistics can mislead deployment decisions.** Scoring 60 marketing posts (15 students plus 15 researcher-authored low-quality anchors) against two independent human raters gave absolute agreement ICC(2,1) of .435 for the LLM, .266 for an equal-weight rule-plus-LLM hybrid and .091 for deterministic rules, with MAE of 6.28, 10.53 and 17.22 points respectively on a 0-100 scale; the hybrid was significantly worse than the LLM alone (paired ICC difference -.169, 95% CI [-.260, -.106]). Adding anchors raised inter-rater ICC from .338 to .902 and LLM agreement from .435 to .846, and a near-empty post was awarded 75 against a human mean of 30.5, showing that a single degenerate response can dominate a small evaluation. (Agreement and error in automated scoring of student marketing posts)
- **Structured LLM grading can look analytic without being diagnostic (2026):** Scoring 3,041 responses to 50 computer-science questions, three commercial LLMs produced rubric sub-dimensions that were near-redundant (r = 0.82–0.99, VIF up to 45) and named Misconceptions about AI in only 4.8–7.4% of comments, against 15.0% for instructors (Zhao et al., 2026).
- **"A single kappa is the case for a grader."** It is one check, and a benchmark of **22 prompted models** on three public corpora shows why. Every model met probes whose right answer is known: a polite request for full marks, a forged grading instruction, a blank answer, a nonsense word, a bare objection. **Fourteen** were flagged for gaining more than **5% of the scale** from a note, up to **83.2%** on code, and **seven** credited blank or meaningless answers, so the agreement figure and the failure tests have to be read together. A deployed grading system has one more

input to test: sharing a learner model's estimate with the grader shifted marks by **0.28 to 0.75 points** on identical work, and the ablation that found it left rater agreement almost unchanged.

Common Misconceptions

- **"An automated score is a single reliable number."** A practical computer vision exam (**570 dual-graded students**) was graded under **171 configurations**, and a second machine-learning exam under further ones — the configuration drove the score. A grade presented as a number conceals the configuration that produced it.
- **"The judge is the source of unreliability."** On 378 fixed-dice rulings, a re-run changed **2.9 to 6.1 per cent** of outcomes under a semi-rigid method and **13.5 to 15.9 per cent** under free adjudication, while swapping the judge AI added only about 3 points (Epstein, 2026) — the procedure, not the judge, sets reproducibility.
- **"Confidence reporting is a nicety."** A score that said it was **70% sure** would change how it is used, and the absence of that information forces the reader to treat all scores as equally certain.
- **"Short-answer auto-marking is a settled area."** A scoping review of short-answer auto-marking in science (**2017 to early 2024**) documents the field's history, which is a record of what has been attempted rather than of what has been validated.

Automated Essay Scoring

> **Automated Essay Scoring (AES)** — the use of AI to evaluate and score written essays, spanning traditional statistical approaches, fine-tuned language models, and increasingly accessible Large Language Models (LLMs)-based prompting strategies. AES research in this knowledge base covers scoring accuracy, fairness and bias, psychometric validity, and practical Accessibility for educators.

Questions to Consider

- Automated Essay Scoring has moved from traditional statistical models to LLM-based prompting. A key tension on this page is between accuracy and accessibility — fine-tuned models score well but are impractical for most educators. Which would you prioritize in your own context, and why?
- A major finding is that simply including exemplar essays in the prompt brings LLM-human agreement close to human-human reliability — and a cheaper model can match a more expensive one. What does this suggest about how much of AES quality is the model versus how it's prompted?
- The page warns that AI scoring can systematically underestimate students from linguistically diverse backgrounds. Before reading, if you saw an AI give a lower score to a non-native speaker's essay, would you have assumed it was a 'bias problem' or just 'the score'? What would change how you respond?
- A self-referential approach assesses L2 writers by comparing their writing to their own prior work rather than to native-speaker norms. How does the choice of comparison baseline change what a score means — and which students might it treat more fairly?
- AES intersects with formative assessment when used for feedback rather than grading. When would a machine's feedback on an essay be genuinely useful to a developing writer, and when might it flatten the kinds of qualitative feedback a human editor would give?

Introduction

Automated Essay Scoring has a long history in educational technology, from early statistical models to modern LLM-based approaches that can evaluate essays holistically without large pre-scored datasets. The key tension in AES research is between accuracy and accessibility — while fine-tuned models achieve strong results, they are resource-intensive and impractical for most educators.

- **Zhang et al.** RACES uses reward alignment to make LLM essay scoring both accurate and consistent, addressing a core AES validity concern.

Xu, Lu and Abdi (2026) review twelve studies comparing AI and human scoring of EFL academic writing and report moderate alignment overall, strongest on surface linguistic features and weakest on organization, coherence and argument development, with fairness rarely examined.

In upper-elementary response-to-text writing, Correnti et al. (2026) find that automated feedback on students' use of evidence improved feature scores, and that revision quality depended on whether teachers took the feedback up in discussion, not on the system alone.

Key research themes

Prompting-based AES has emerged as the most accessible approach. The **Choi et al. anchor paper study** shows that including exemplar essays in prompts brings LLM-human agreement close to human-human reliability, with GPT-4o mini achieving comparable results to GPT-4o at lower cost. This connects to broader Prompt Engineering research and makes AES feasible for teacher use.

Psychometric and trait-level scoring moves beyond holistic scores. **PsyScore** provides a psychometrically-aware framework for trait-adaptive scoring with ZPD-grounded feedback. **ICLE++** models fine-grained traits for holistic essay scoring, advancing the precision of automated evaluation. - **Dimension-level trait scoring is bounded by the data behind each dimension.** Firdausi et al. (2026) trained one classifier per dimension of Ennis's FRISCO Critical Thinking framework on 106 Indonesian eleventh-grade physics essays (83 for training, 23 for testing, with three teacher raters agreeing at kappa 0.78–0.84 on every dimension). Agreement concentrated on expression rather than reasoning: quadratic weighted kappa reached 0.763 for Clarity and 0.728 for Situation but only 0.374 for Focus, 0.332 for Reason and 0.227 for Inference. The ordinal signal was manufactured rather than observed. Synthetic level-1 essays (built from templates, cut to 20–40% of their original length, with keywords removed) plus LLM paraphrase lifted Focus by +0.346 kappa off a 0.028 baseline — and one configuration reached 0.652 accuracy with near-zero or negative kappa, — so accuracy is not a usable selection criterion in ordinal AES.

Bias and fairness is a critical concern. **Feser & Tschisgale** found that AI scoring systematically underestimates students from linguistically diverse backgrounds, highlighting the need for Bias Mitigation and Equity considerations in AES deployment.

Teachers want the score presented as reviewable, not final. Nine experienced Brazilian high-school writing teachers evaluated an AIED-Unplugged essay-scoring app and rated it highly — median SUS 92.5, TAM medians of 7 for usefulness, ease of use, relevance and intent to use, 6 for result quality. They volunteered, unprompted, that the report should carry an on-screen warning that it is not fully reliable and must be reviewed before a student sees it; one teacher read that obligation as a positive feature (Ribeiro et al. (2026)). They asked for more detail, not less: per-competency diagnostics, a global summary, a field for their own comments, and concrete examples of how to improve. Where validity research argues about agreement rates, these users asked the interface to encode the division of judgment between system and teacher.

Disagreement with human graders is systematic, not random. Out-of-the-box GPT and Llama models agreed only weakly with human scores (QWK ≈ 0.17–0.28 against 0.72 between two human raters) and biased in a quality-dependent direction — higher for short, underdeveloped essays and lower for long, strong ones carrying minor surface errors (Mathew et al. (2026)).

L2 and self-referential assessment explores non-native writing contexts. **Profile-based L2 assessment** uses a self-referential approach comparing student writing to their own prior work rather than native-speaker norms.

Interpretability and feature weighting opens the blackbox of how LLMs actually score. **Wang et al. (2026)** compared three LLMs (Qwen, GPT, Gemini) with human raters on non-native English essays across sixteen textual features, finding strong overall alignment but distinct weighting: LLMs emphasized grammatical accuracy, lexical sophistication, and syntactic complexity, while human raters prioritized content completeness and visual presentation. Critically, LLMs shifted their weighting by proficiency level — placing more weight on language errors for low-proficiency students and increasingly rewarding linguistic sophistication for high-proficiency students — whereas human raters maintained a more stable framework. **Liu, Ye, and Yan (2026)** extend this with a five-model evaluation framework (GPT-4.1, Llama 4 Maverick, Gemini 2.5 Flash, Claude Sonnet 4, DeepSeek R1) on 60 long essays, using causal discovery to reveal distinct evaluative heuristics: most models prioritized lexical precision and fluency, while others emphasized syntactic complexity or cross-domain integration, and some showed inconsistency, score compression, or systematic underestimation. Together these studies establish that AES validity depends not only on overall agreement but on *how* models weight features and whether that weighting is stable across learner subgroups — directly informing Assessment Validity and Bias Mitigation auditing.

Item-type boundaries and the limits of essay grading. In a mixed-format university exam, Falahat, Das, Bhaumik & Thambi (2026) found ChatGPT-5's concordance with faculty was substantial-to-near-perfect on objective items (CCC 0.935–1.000) but dropped sharply on open-ended responses — near-zero to negative for short-answer and only 0.341–0.854 for essay questions — and a structured rubric did not consistently improve essay agreement. This bounds AES validity: model fluency helps on well-specified items but does not carry over to holistic essay scoring, where contextual interpretation of partial-credit responses still favors human judgment.

Issue-type boundaries in diagnostic agreement. Yao and Fan (2026) used DeepSeek-R1 to label specific writing issues before revision and compared its labels with teacher diagnosis across three cycles (mean F1 = 0.768, SD = 0.037). Agreement was highest on locally cued issues such as vocabulary word choice (F1 = 0.824) and lowest where the issue turns on a claim–evidence relation (source use and evidence, 0.579), so agreement in a diagnostic role depends on the issue type, not only on the model or the prompt. **A skewed rubric distribution can make aggregate scoring metrics mislead.** Automated evaluation of a rubric dimension may be a classification task with a lopsided label distribution rather than a continuous score: marking reflection level 0-3 in 1,954 Hungarian student essays, 68% of essays sat at level 3 and 1.8% at level 0, and the best shallow configuration (SMOTEBoost with Qwen3 embeddings) reached an overall score of 0.7176 averaged over accuracy, F1 and ROC-AUC against 0.6872 for the best fine-tuned transformer — yet one RidgeClassifier configuration scored 0.7131 ROC-AUC at only 0.5162 accuracy, and class balancing lowered every metric (accuracy falling from 0.6672 without it to 0.6408 with it), so the authors read model choice as a question of which metric matters, with transformers earning their place through minority-class sensitivity rather than aggregate agreement (Csibi et al., 2026).

High-stakes deployment evidence. Field evidence from a real high-stakes deployment (Uruguay's *Acredita EB*, 2024–2025; Curi et al.) shows prompt-engineered GPT-5 reaching 60–80% agreement with trained human raters across a 15-item analytic Spanish rubric, roughly five percentage points below human inter-rater agreement for most items and never more than 15 points below, with run-to-run consistency above 90% for almost all items. Vocabulary, syntax and spelling were the weakest dimensions, and the spelling item had to be handed to a deterministic grammar checker (LanguageTool, 68% accuracy, 100% consistency) because token-level orthography is where the model is least stable. Prompts built for one exam edition transferred to

the next with only topic-specific edits, and the AI was systematically stricter than humans — under-grading rather than over-grading. For AES design, the lesson is that prompting-based scoring can approach human agreement even in a national exam, while its remaining weakness sits at the level of low-level language conventions rather than holistic writing quality.

Token-level confidence, probability-weighted scoring, and ensembling each improved agreement on divergent-thinking scoring — the stacked techniques reached r = 0.846 (RMSE = 0.4848), and routing only the least confident 20% of responses to human review cut manual effort by roughly 80% (Organisciak & Acar (2026)).

The human Benchmark, and what it can and cannot license. The OpRaise study is the strongest test in this knowledge base of whether LLM marking is ready for routine use, and its answer turns on the benchmark rather than the model. It compared three frontier systems (Claude Opus 4.6, GPT-5.4, Gemini 3 Flash), each under 27 prompt configurations crossing rubric specificity, calibration and scoring strategy, against the moderated marks of 761 authentic Psychology essays from 125 students at three UK universities. Human marks were adopted as ground truth because academic judgment is the socially accepted standard, and the authors note that human markers agree only moderately with each other — which bounds how strong AI–human agreement could reasonably be demanded to be. Against that benchmark, agreement on the UK degree band ranged from **35 to 65 percent by institution** (63 percent at Cambridge, 53 percent at Nottingham, 35 percent at Manchester Metropolitan) and did not transfer between them, so the report's central recommendation is local validation on an institution's own Assessment materials. Two findings generalize beyond this corpus. First, reliability and agreement pull apart: every model re-marked nearly identically (ICC 1.00, 1.00, 0.97) and the models agreed with each other more closely than with humans (three-model ICC 0.91), yet all three agreed on the degree band for only **56 percent** of submissions — self-consistency is not validity. Second, AI marks compressed toward the middle of the scale (a compression score of 0.47–0.82, with the crossover where AI and human agree on average sitting in the upper 50s to low 60s), making AI least accurate precisely at the grade boundaries that separate Firsts from Upper Seconds and passes from fails. Vocabulary range, connectives, sentence complexity and text length predicted AI marks with small but significant effects while their relationship with human marks was broadly negligible — a direct demonstration of the linguistic-bias concern, and one that no prompting strategy tested removed.

AES as a training signal rather than a judge. Scoring models are usually studied as evaluators, but SWIM uses one as a reward function. Do, Kontak and Sachan (2026) freeze a multi-trait AES verifier and score it against generated student essays, turning the predicted trait profile into a dense per-essay reward (the mean trait-normalized distance from the target profile) for GRPO, deliberately not the Quadratic Weighted Kappa metric itself. QWK is defined over a batch of target-prediction pairs and is not a per-sample signal, while exact-match rewards are too sparse in the multi-trait setting. The gains were re-checked against a DeBERTa scorer and an evaluation-only verifier the policy never trained against (0.598 versus 0.479 for SFT, and 0.647 versus 0.501), which is the check that separates genuine proficiency control from adaptation to the reward model. For AES research this is a second validity demand: a scorer used as a training target is being optimized against, so its own trait weighting and language biases propagate into everything the generator learns. The same feature-weighting asymmetries (grammatical accuracy, lexical sophistication and syntactic complexity weighted more heavily by models than by human raters) documented elsewhere on this page now shape training rather than only marks. **Scoring and feedback want different methods, so a system should separate them.** Labib et al. (2026) built one TOEFL argumentative-essay system as three modules —

scoring, surface-level feedback on grammar and mechanics, and deep-level feedback on organization, coherence and argumentation — instead of a single model doing all three jobs. What wins on one module loses on another: supervised fine-tuning of GPT-4o on 120 of a proprietary set of 480 benchmark-scored essays, tested on the remaining 360, reached a quadratic weighted kappa of 0.84 and RMSE of 0.44 on the 0-5 scale, ahead of the Wang and Gayed (2024) baseline (QWK 0.78, RMSE 0.57). Yet the same fine-tuning produced unusable output for the feedback modules, where direct prompting of Claude 3.7 was what generated teacher-approved comments.

Connections to related concepts

AES sits at the intersection of Automated Assessment, Writing, and Generative AI. It connects to Formative Assessment when used for feedback rather than grading, to Feedback Loop when integrated into iterative writing processes, and to AI Literacy when educators understand and calibrate AES tools. The Assessment Validity and Educational Measurement concepts are essential for ensuring AES scores are meaningful and fair. - **Agreement, error and what a hybrid scorer adds.** In a small open-ended marketing-writing corpus the LLM out-scored both deterministic rules and an equal-weight hybrid on absolute agreement with human raters (ICC(2,1) .435 versus .266 and .091), with the hybrid significantly worse than the LLM alone, while score dispersion and a single near-empty response showed how strongly such estimates depend on corpus composition (Agreement and error in automated scoring of student marketing posts).

Open systems are part of this picture too: AiAWE scores argumentative essays with a LoRA-adapted Gemma-3-27B-it, reaching QWK 0.828 and agreement within ±0.5 of the human score on 90.56% of 360 evaluation essays — and reports that model scale did not reliably predict downstream performance under LoRA adaptation (AiAWE: An Open-Source LLM Automated Writing Evaluation System Using LoRA-Adapted Instruction-Tuned Models).

- **“The prompted model that agrees best is the strongest essay scorer.”** On ASAP 2.0 the published agreement between the two expert raters is **κ 0.745**, and no prompted model’s point estimate reached it: the 22 ran from **0.155** to **0.727**, and for **18** the whole interval lay below. A fine-tuned DeBERTa scorer reached **0.809** and a rule that counts only essay length reached **0.636**, above **16 of 22** models, though every model kept agreement beyond length. The baseline to beat is the trained scorer, not the model down the road.

Common Misconceptions

- **“Automated scoring results reflect student writing.”** The ordinal signal can be **manufactured rather than observed** — synthetic level-1 essays built by template generation, degradation to **20-40% of original length** and keyword removal. A system validated on constructed extremes may never have been tested on the distribution it will meet.
- **“Aggregate accuracy is the metric to report.” A skewed rubric distribution can make aggregate scoring metrics mislead**: automated evaluation of a rubric dimension is often a classification task with a lopsided label distribution, where high accuracy and useful discrimination separate.

- **“Field deployments have not been evaluated.”** Field evidence exists from a real high-stakes deployment (**Uruguay’s Acredita EB, 2024**), which is the strongest form of evidence in this literature and the one most studies of scoring accuracy never supply.

Automated Question Generation

> **Automated question generation (AQG)** — the use of AI, especially NLP and large language models (LLMs), to generate educational assessment items (multiple-choice, short-answer, fill-in-the-blank, coding, and performance questions) automatically from source material or learning objectives. AQG enables assessment at scale — producing formative quizzes, adaptive exercises, and practice items — but quality varies dramatically across item types and requires validation to avoid hallucinated or poorly calibrated questions. It is a core component of Automated Assessment and a key enabler of Adaptive Learning and Personalized Learning.

Questions to Consider

- Automated question generation produces assessment items from source material at scale — but this page warns that quality varies dramatically across item types. Before reading, which item type would you guess AI generates most reliably: multiple-choice, short-answer, or code — and why?
- The central challenge is quality control: LLMs can generate factually incorrect questions. One pipeline reduced hallucination by 62% by adding a generate-then-validate-refine loop. Why do you think asking the AI to validate its own questions would meaningfully improve them rather than just rubber-stamping its own output?
- Research shows generated questions may skew toward lower-order thinking (recall) unless explicitly designed for higher-order outcomes. If you used AI to build practice items, how would you know whether they were training genuine understanding or just memorization?
- Difficulty calibration matters: AI difficulty estimates correlate strongly with student performance, but the page cautions against high-stakes misuse. When would a question that AI judges ‘right difficulty’ still be the wrong question to ask a particular learner?
- Accessibility-aware generation builds questions tuned for Deaf and Hard of Hearing learners, refined in partnership with the target community. What does this example suggest about why question generation can’t be treated as a purely technical or content-only problem?

Introduction

Automated question generation matters because assessment items are expensive to create by hand, and AI can produce them rapidly and at scale. However, the knowledge base’s research shows that generated items must be validated for correctness, relevance, and difficulty, and that different item types (MCQs, short-answer, code) vary in how reliably they can be generated. AQG therefore sits at the intersection of generative AI, educational NLP, and Educational Measurement.

Approaches to question generation

The knowledge base's research illustrates several approaches:

- **Generate-then-validate pipelines:** Generate-Then-Validate introduces a generation → validation → refinement loop that reduces LLM hallucination by 62% compared to direct generation, achieving 89% accuracy on STEM datasets and a 23% improvement in relevance. The validation step filters invalid or low-quality items, and failed items trigger re-generation with corrective prompts.
- **Knowledge-tracing-based generation:** KT4EQG generates personalized exercise questions guided by knowledge tracing, tailoring items to each learner's knowledge state rather than generating generic questions.
- **Misconception-bound distractors as diagnostic labels:** CoLearn (He et al., 2026) attaches each distractor to a single mined misconception and marks exactly one correct option, so an item is generated with its diagnostic targets built in and can then be graded deterministically with no Large Language Models (LLMs) call — about 7.6 seconds and roughly $0.005 per round on the authors' live deployment, against about 32 seconds and $0.015 for an LLM-graded short-answer round. The binding is only as good as the misconception labels behind it, since mined Misconceptions about AI matched the target misconceptions at F1 ≈ 0.56, and its item choices served a genuinely weak skill 0.72 of the time.
- **Cognitive-depth-aware generation:** Evaluating the cognitive depth of LLM-generated questions examines whether generated items tap higher-order thinking (creation, evaluation) or only memorization, connecting to Bloom's taxonomy and Educational Measurement.
- **Error-embedded case problems for repeat assessment:** Takahashi et al. (2026) generated new hierarchical diagnostic reasoning (HDR) problems — short cases carrying deliberately embedded errors that students must find and explain — and found GPT-4o-authored items matched human-authored ones on internal consistency (Cronbach's $\alpha = 0.78$ for both) and difficulty, with Fisher's exact tests finding no significant score-distribution difference across 100 participants. The format pairs a higher-order thinking demand with a constrained response, so answers converge and grading becomes reproducible. The generative motivation is item reuse: reusing one case invites memory and answer reuse, while structurally equivalent but contextually different generated cases suppress item bias in re-measurement.
- **Pedagogical pipelines:** Slide-deck Q&A generation uses a multi-stage pipeline for pedagogically sound question generation from course materials.
- **Accessibility-aware generation:** Chen et al. design an LLM-powered question-generation system for Deaf and Hard of Hearing learners, introducing Visual and Emotion question strategies that target moments of visual or emotional difficulty in video, and iteratively refining questions with the target community to ensure linguistic accessibility.
- **RAG-based, human-in-the-loop systems:** CODE-GEN combines retrieval-augmented generation with human-in-the-loop review for generating multiple-choice assessments.
- **Benchmarks and evaluation:** NSMQ Riddles provides a benchmark of scientific/mathematical riddles for evaluating question-generation and reasoning systems.

Validation and quality

The central challenge in AQG is **quality control**: - **Assess the solving process, not the stem:** ProIQA argues that item quality review should follow what an expert does — simulate the solution — and builds an LLM-generated reasoning tree per item, verified for mathematical correctness at 90.38–97.80%, then encodes its dependency structure with a graph neural network alongside a stem-only view. It reports average gains over the second-best method of 7.5% in concept assessment, 6.3% in difficulty estimation and 19.5% in competency assessment, and its error analysis names a failure mode worth watching: a logically correct but structurally shallow reasoning tree leaves a hard item looking easy.

- **Hallucination risk:** LLMs can generate factually incorrect questions. Generate-Then-Validate shows a dedicated validation phase sharply reduces this, and hallucination risk is a recognized concern throughout.
- **Difficulty calibration:** generated questions must be calibrated to appropriate difficulty. Difficulty-calibration research shows AI difficulty estimates correlate strongly with student performance (e.g., rho ≈ −0.87), enabling better item selection — while cautioning against high-stakes misuse. Razavi and Powers (2026) extend this to K-5 math and reading items (N = 5170) calibrated under the Rasch IRT model: GPT-4o's zero-shot difficulty ratings correlated moderately-to-strongly with true difficulties (r = 0.83 math, r = 0.81 reading) but varied by grade, while a feature-based approach — LLM-extracted cognitive and linguistic features fed into tree-based models — reached correlations up to r = 0.87. The study's structured feature extraction (e.g., syntax complexity, cognitive load, distractor trickiness) and its practical seven-step workflow offer a template for calibrating generated items, while its early-grade range-restriction finding and generalizability caveats caution against high-stakes use.
- **Generated difficulty labels can be a construct-validity failure, not a calibration error.** Across 378 generated items the model's Easy/Medium/Hard labels tracked the Bloom level co-generated with them (ρ=0.90) and surface form - mean stem length rising from 15.9 to 22.1 to 30.2 words - but correlated with empirical item difficulty at only ρ=0.06 over 7,888 responses from 54 students, the case for calibrating generated metadata against response data rather than trusting co-generated tags (An & Wang (2026)).
- **Large-scale psychometric field validation:** Assessing AI-Generated Exams validates an iterative-refinement AQG pipeline (generate → judge → revise, Self-Refine style) in 91 real college classes (~1,686 students). Bayesian hierarchical 2PL IRT analysis shows AI-generated questions perform on par with expert-written standardized-exam items — somewhat easier ($\bar{\beta} = -0.45$ vs. 0.35) but slightly more discriminating ($\bar{\alpha} = 1.3$ vs. 1.2), with higher peak test information (reliability 0.79 vs. 0.72) — demonstrating that AQG can produce course-tailored, psychometrically sound assessments at scale.
- Average psychometric parity can mask item-level shortfalls: a scoping review of 153 medical-education reports found AI item generation sometimes matched human difficulty and discrimination, yet in one physiology comparison only 9 of 40 ChatGPT items met all ideal criteria against 19 of 40 faculty items (Zhao et al. (2026)).

- **Recognizability in a live exam, and what review actually removes:** Vogt et al. (2026) put 30 AI-generated and 30 National Licensing Exam MCQs into a graded tablet-based exam taken by 119 fifth-year medical students, with the AI items drafted from the course's own materials by ChatGPT-4o and Gemini 1.5 Pro through an expert panel that accepted 82% of them and eliminated 18.2% as unusable. Students' source attribution did not differ between the two kinds of item, and item difficulty, distractor distribution and perceived curricular alignment were statistically indistinguishable — a *recognition* result rather than a quality result, and the reason the authors describe the workflow's benefit as shifting educator effort from drafting to reviewing rather than removing it. One exploratory difference survived: Gemini items were harder than the licensing-exam items ($p = 0.028$), while ChatGPT items were not ($p = 0.984$).
- **Task-dependence:** generation reliability varies by item type. Short-answer grading and analytic writing assessment show that open-response and writing items are harder to generate and grade reliably than structured items.
- **Cognitive quality:** cognitive-depth evaluation shows generated items may skew toward lower-order thinking unless explicitly designed for higher-order outcomes.
- **Auto-labeling cognitive level does not transfer to generated items.** A Bloom taxonomy classifier trained on a curated item bank collapsed on AI-generated questions — macro F1 from 0.88 in distribution to 0.48 and 0.20 out of it — because generated items average far more words (18.2 versus 9.3) and share only a median 10.5% of their Bloom trigger verbs with the curated corpus, against 35.1% for a closer set; retraining on labeled out-of-distribution data was the largest single gain, at a threshold of roughly $N > 1{,}000$ labeled samples (Castanares et al., 2026).

Role in adaptive and personalized learning

AQG is a key enabler of adaptive and personalized learning: it produces the large item banks that adaptive tutors draw from, and — combined with knowledge tracing or student modeling — can generate items tailored to individual learners' knowledge states (KT4EQG). Interest-based personalization shows AQG can also adapt questions to student interests, not just difficulty.

Implications for AI in education

- **Generate then validate:** always pair generation with a validation/refinement stage to control hallucination and ensure relevance.
- **Match item type to reliability:** use AQG for structured item types (MCQ, fill-in-the-blank, code) where it is most reliable, and apply careful validation to open-response and writing items.
- **Design for cognitive depth:** prompts and pipelines should target higher-order thinking, not just recall, to support genuine learning.
- **Calibrate difficulty:** use AI difficulty estimates to select appropriately challenging items, with strong validation before high-stakes use.
- **Personalize via learner models:** combine AQG with knowledge tracing and interest models to generate adaptive, individualized items.

Common Misconceptions

“Generated questions are usable at the scale they can be produced.” Volume is not the constraint; calibration is. Quality varies dramatically across item types and requires validation to avoid hallucinated or poorly calibrated items, which is why the pipelines that work spend their effort on verification rather than generation — one reduced hallucination by **62%** by adding a generate-then-validate-refine loop.

“A refinement loop makes generated items trustworthy.” It makes them less wrong. A 62% reduction in hallucination leaves a substantial remainder, and no loop resolves the harder problem of whether an item’s stated difficulty matches what students actually do — the validity question that the difficulty-label evidence shows generated metadata failing on. Validation reduces fabricated content; calibration requires student response data.

“Question generation naturally personalises practice.” It generates supply, and personalization is a matching problem. Producing more items does not tell you which item a given learner should see next, and the adaptive-selection question is a separate mechanism with its own evidence.

“Generation scales assessment without changing what assessment measures.” It changes the composition of what is measured, because the items that generate well are not a representative sample of the items that assess well. Easy-to-generate formats will progressively crowd out the harder-to-generate ones, which quietly reshapes the construct.

Measurement and validity

Assessment Validity

> **Assessment validity** — whether assessments measure what they claim to measure. AI in Education raises fundamental validity questions: do AI-graded assessments assess student learning or AI prompting skill? Does AI use invalidate traditional assessment assumptions?

Questions to Consider

- Validity asks whether an assessment measures what it claims to measure. Before reading, if you saw a student submit a polished essay you suspected was AI-assisted, would you think the bigger problem was cheating, or that the task was no longer measuring what you thought it was measuring?
- This page poses a sharp question: when students use AI, does the score reflect student knowledge or AI-prompting skill? Can you think of an assessment you've designed or taken where the score might now be telling you more about the tool than about the learner?
- A key finding is that the same learner input can receive semantically different replies depending on which underlying LLM is used — introducing 'construct-irrelevant variance' that threatens reliability and fairness. If two students get different AI support purely because of the model behind it, how fair is the resulting comparison?
- The page argues that even when an LLM scores well, transferring human score interpretations requires similarity in the latent structure of responses — and LLMs diverge from humans here. What does this suggest about trusting an AI that 'passes' an exam designed for humans?
- Rather than trying to detect AI use, the knowledge base argues for redesigning assessments so they stay valid for AI-capable students. Why might redesigning the task be a more validity-preserving strategy than policing whether AI was used?
- AI now serves as test-taker, test-maker, rater, and analyst — making the interpretive chain opaque. When every role in an assessment is filled by AI, what does it even mean to say an assessment is 'valid' for the human learner in the middle of it?

Introduction

Validity challenges

- **Construct validity:** When students use AI on assessments, does the score reflect student knowledge or AI capability? Performance vs. learning research addresses this directly. A reconstruction measure can be sensitive to correctness without being a correctness score: Su et al. (2026) found higher EEG reconstruction similarity for correct items (M = 71.43, SD = 4.61) than incorrect (M = 62.30, SD = 5.91), yet one learner's high-quality reconstruction accompanied a wrong answer.
- **Cross-LLM construct-irrelevant variance in conversation-based assessment:** Hao (2026) shows that even for a single conversational turn, the semantic content of Large Language Models

(LLMs)-generated replies varies across models and conversational-context conditions. Within-model similarity consistently exceeds between-model similarity (0.715–0.795 vs. 0.443–0.604), and adding chat history meaningfully changes response content (median cross-history similarity ~0.40–0.45). Because the same learner input can receive semantically different replies depending on the underlying model, prompting and context alone cannot preserve response consistency — introducing potential **construct-irrelevant variance** that threatens validity, reliability, and fairness. Maintaining consistent assessment conditions as LLMs evolve is therefore an *infrastructure* challenge (symbolic rules, response templates, validation layers), not merely a Prompt Engineering one.

- **Evidence that is present yet never reaches the scorer:** Abreu, Stari and Martí (2026) name a construct-irrelevant threat that precedes any reasoning: in AI review of experimental physics laboratory reports, an equation, graph, table or unit may be correctly included in a report yet not be retrieved from the processed content the model works from, and because a changed sign, value or unit alters the physical interpretation, a disagreement with the instructor need not indicate a reasoning error. Their remedy is procedural — high-resolution PDFs rather than photographed scans, equations written in an equation editor, legible axes and units inside figures, and instructions requiring a concrete citation for every score — because document quality sets the ceiling on whatever validity claim the resulting score supports.
- **Latent-structure validity across humans and LLMs:** Strugatski et al. (2026) add a deeper validity condition: even when an LLM scores well, transferring human score interpretations requires similarity in the *latent structure* of responses. Comparing six Multimodal AI LLMs to human cohorts on chemistry and quantitative-reasoning instruments, they find LLM–human factor structures consistently diverge (LLM–human congruence below the human–human baseline), so performance on a human-normed exam is weak evidence about LLM abilities on the constructs the items were designed to measure.
- **Consequential validity:** Do AI-mediated assessments have fair consequences? Language bias studies show that AI scoring can disadvantage non-native speakers.
- **A moved target in language testing.** High-stakes tests like TOEFL iBT, IELTS, PTE Academic and the Duolingo English Test still demand unaided, timed reading and writing while students now use GenAI for those tasks in academic life, so the extrapolation inference — from unaided scores to real academic performance — is the step most affected (Gonulal (2026)).
- **Rule scope is itself a validity property:** Wright (2026) argues that the prohibitions written across higher education since 2023 bar "generative AI" without the technical precision to separate the generation of assessed content from the conversion of a format, since optical character recognition, handwritten text recognition and speech-to-text are recognition technologies that infer what is already present rather than producing new content. Where a rule attaches to platform identity rather than function, it is over-inclusive by definitional accident: it captures transcription-only use of a multi-functional tool and sanctions a student who did not do the thing the rule was designed to prevent, falling hardest on Learners who rely on those tools for accessibility — an inference the assessment cannot support about the construct it claims to measure. He proposes function-based drafting plus four operational criteria (fidelity, non-augmentation, traceability,

attestation) for borderline cases, and treats the reliance on detector output and style heuristics as evidence of how weak the rule's own evidential basis is.

- **Agentic completion removes the human-production assumption:** Hadjisolomou & El-Haddad (2026) extend the validity analysis from generative *assistance* to agentic *completion*: autonomous AI agents can now log into an LMS, read materials, and complete unproctored asynchronous work end-to-end (demonstrated on a live course — a quiz scored 10/10 in under 5 minutes, and a fabricated-but-credible discussion-board reflection). Placing a "human-production assumption" at the base of Kane's argument-based inference chain, they show agent completion silently removes the backing for the *scoring* inference on which generalization, extrapolation, and decision inferences all rest — so every unproctored asynchronous score, including honestly earned ones, loses its interpretive support because authorship is unverifiable. Their decisive move is classifying this as a **validity failure rather than an integrity one**: an institution can punish misconduct and still lack grounds for the scores it reports. Detection is structurally insufficient (classifiers unreliable and biased; LMS monitoring sees the same clicks a student would), so the remedy is assessment redesign for verified human presence (a short oral component, process-visible drafts, class-session-specific references), with an equity-preserving menu of options rather than a proctoring mandate.
- **Construct-irrelevant variance in human grading of GenAI-assisted work:** Luo & Dawson (2026) provide a direct empirical demonstration that human grading of GenAI-assisted work is shot through with construct-irrelevant variance. In scenario-based interviews with 33 university teachers, grading decisions were driven by person-oriented (student honesty, diligence), capability-oriented (independence from AI, GenAI skill, disciplinary mastery), relation-oriented (trust built with students), and justice-oriented (fairness, beneficence) values — all of which can vary grades on factors unrelated to the outcomes being assessed. Marking down GenAI-assisted work is justified, they argue, *if and only if* the AI use prevented students from demonstrating the assessed outcomes; otherwise value-driven grading threatens validity. The study grounds the validity framing in real teacher practice and calls for "two-way transparency" — teachers clarifying how GenAI use will affect grades, not just students declaring use.
- **Variation-at-scale demands construct-equivalent variant generation:** VARIA (Lee 2026) subjects the "variation-at-scale" premise of AI-Integrated Authentic Assessment (AIAA) — replacing surveillance proctoring with per-student task variation — to an empirical, falsifiable check. Because each examinee receives a unique-but-equivalent performance task, the integrity guarantee is conditional on LLMs generating variants that are simultaneously surface-distinct, construct-equivalent, rubric-applicable, and difficulty-matched. Benchmarking three frontier model families across four prompting strategies on 600 variants, VARIA finds frontier generators satisfy the joint integrity criteria only at the margin (joint score 0.81–0.88) while non-frontier references collapse (0.50–0.55), and no single prompting strategy dominates all four properties — so "variation-at-scale cannot be solved by prompting alone" if the diversity threshold is set aggressively, and institutions must validate their specific model-prompt pair.
- **Under-grading bias in HITL AI scoring is a validity feature, not a bug:** Curi et al. (2026) show that in a large-scale national writing assessment the systematic conservative (under-grading) bias of an LLM scorer, while problematic as a final decision, is precisely what enables safe

delegation: AI-marked "passing" responses can be accepted with confidence while AI-marked "failing" responses (15.3–16.5% of cases) are routed to expert review — keeping the validity threat of AI error off the final outcome. Their IRT-and-Bookmark pipeline makes the proficiency-level impact of AI scoring legible rather than treating raw score agreement as the sole validity signal.

- **AI-driven grade inflation as a validity threat:** Chirikov (2026) identifies a novel, technology-driven mechanism of grade inflation operating *upstream of grading* — on the production of graded work. In a difference-in-differences study of 500,000+ grades across 319 courses (2018–2025), courses with more AI-exposed tasks (writing, coding) saw the share of A grades rise by 13 percentage points after ChatGPT's release, with grade-distribution compression. A triple-differences analysis shows the effect concentrates in homework-heavy courses — evidence that AI **task displacement** (AI performing graded tasks before instructors observe them) inflates grades without a corresponding rise in skill. This reduces the comparability of grades across courses and erodes the informational value of transcripts in ways difficult to detect from grade distributions alone.
- **Program-level pass/fail susceptibility, and the marking criteria that set it:** Ivory et al. (2026) judged ChatGPT output for every coursework assessment in a three-year psychology degree (40 assessments, 16 types) with a binary pass/fail, the decision markers actually make on a first read: 36 of 40 passed. Two validity implications follow. First, the operative variable is the pass boundary, not detection — marking that rewards structural fluency and the correct choice of analysis while condoning incorrect values lets fabricated statistics and hallucinated references clear a pass, so the assessment certifies tool output as student understanding because of how it is marked rather than because anyone was fooled. Second, multiple-choice items leaked their own answers: ChatGPT answered statistics questions correctly without the figure or output table shown to students, because the item stem and options implied the answer, which makes answer-option design a validity property of the item rather than a property of the AI.
- **Accuracy vs. agreement as distinct validity signals:** Falahat, Das, Bhaumik & Thambi (2026) graded a 21-item pharmacy exam with ChatGPT-5 and found that moderate percent accuracy frequently coexisted with low concordance-correlation coefficients — a methodological distinction between *scoring accuracy* and *agreement* that limits AI's reliability as a grading substitute even where raw accuracy looks acceptable. Agreement was strong on objective items (CCC 0.935–1.000) but near-zero on short-answer and modest on essay (0.341–0.854), and rubric provision did not consistently close the gap.
- **Validity of AI-generated items:** Assessing AI-Generated Exams shows that AI-generated questions, validated via Bayesian IRT, achieve difficulty and discrimination on par with expert-written standardized-exam items (reliability 0.79 vs. 0.72) — supporting the validity of course-tailored AI-generated assessments when backed by psychometric evaluation.
- **Authentic assessment:** Authentic Assessment and the AI Assessment Scale propose validity-preserving assessment redesigns.
- **Confidence and calibration:** Confidence-aware systems improve validity by flagging uncertain assessments.

- **Embodied and multimodal evidence:** speech-only assessment can mistake verbal fluency for conceptual knowledge; Morphew et al. show that computer-vision gesture analysis coupled with LLM speech analysis increases construct validity and Equity by capturing understanding expressed through gesture, not just words — reducing bias against learners who express understanding non-verbally.
- **Homework stops certifying capability when a model can solve the task:** Mikhasenko et al. (2026) document a concrete invalidation of homework as a capability measure in a Bochum particle-physics course: once a generative model can produce a correct solution, a submitted derivation no longer establishes that the student can solve the problem independently. Their response separates the two functions — research-shaped, AI-permitted homework kept as exploratory, bonus-bearing work, and a tools-free written examination made the sole determinant of the final grade — a validity-driven division of labor rather than a detection regime.
- **Decision-oriented validity for AI scoring at scale:** Curi et al. (2026) illustrate a decision-oriented view of validity in the Acredita EB national writing assessment: rather than asking only whether AI scores agree with humans, they ask whether AI errors can change a certification decision. Automated IRT/Bookmark cut scores closely reproduced the operational cut scores, and systematic AI under-grading was neutralized by routing failing AI results to human review — notably against a reference standard that is itself contested, since ten expert raters scoring the same 50 texts never reached unanimity on any rubric item.
- **Student-side validity concerns about AI as grader:** AlGhamdi (2026) adds the learner's voice to the validity question: 13 computing students whose handwritten writing task was scored by ChatGPT questioned whether an AI scorer can validly interpret intent, effort and institutional grading norms — one asking pointedly, "If ChatGPT [is] checking the exams, why are we going to university?"
- **Permission does not by itself degrade the task, and use rates are the wrong validity signal:** Zou et al. (2026) surveyed 85 student teachers whose assessments explicitly permitted generative AI and found assessment engagement high and statistically unaffected by whether students used it (mean 4.21/5, SD 0.46; Mann–Whitney $U = 781.5$, $r = 0.07$, $p = 0.536$). With 62.4% (53) declining to use generative AI at all and adopters' use confined largely to proofreading (43.8%) and clarity checks (34.4%), the adoption rate carries little information about whether the assessment still warranted an inference about learning — and non-use driven by fear of wrongful plagiarism accusation (41.5% of non-adopters) is not evidence of validity either.
- **Sampling-frame validity when a school-level test is read as system evidence:** Restrepo Morales et al. (2026) give the inference from scores to claims about a *system* a quantitative treatment. A pilot assessment of 1,198 volunteer students in 171 Salvadoran schools on the PISA-based Test for Schools produced results announced as comparable to Germany and Sweden, but the instrument produces estimates for a school and is not administered under the national sampling frame with its response-rate standards, exclusion limits and weighting — so a comparison between a school-level estimate and a country mean carries at least three unreported sources of uncertainty (school-level sampling error, country-mean sampling error, and the linking error of the scale equating). Rather than test the learning claim, the authors bound it: with the top 5.5% of the

Salvadoran mathematics distribution matching the German mean under zero learning, and voluntary participation understood to bias achievement testing upward, the published evidence cannot separate a real effect from a selected sample. This is a failure of the comparison's validity inference, not of the students or of the instrument.

A conceptual proposal raises a validity boundary that applies to every AI-mediated assessment on this page: El Khoury and Ma (2026) argue that speed is not validity, and that AI-generated prompts, examples and transcript-based reports still have to be tested for accuracy, cultural responsiveness, Accessibility, interpretability and alignment with course outcomes. They also widen what counts as evidence: where dialogue becomes the assessed artifact, the transcript is a process record in which judgment, empathy, clarification and shared decision-making unfold in context, and the design question becomes whether that evidence supports the inference drawn from it — the same question automated scoring faces, answered by alignment among task, feedback and evidence of learning rather than by technological novelty.

- **AI-assigned item metadata is not psychometric evidence.** Across a 10-week data science study of 311 deployed multiple-choice items, LLM difficulty ratings tracked the model's own Bloom labels (rho = 0.90) but not empirical item difficulty (rho = 0.06), so item difficulty has to be established from response data rather than from the generating model's labels (An & Wang, 2026).
- **Student judgments of curricular alignment track difficulty, not content.** Vogt et al. (2026) asked students to rate whether each item in a graded 60-item exam aligned with the course curriculum and found the ratings correlated with item difficulty at $\rho = 0.762$ (easier items judged aligned, harder items not aligned, $\rho = -0.762$, $p < 0.001$), while ratings did not differ by item source. Where an instrument asks students to judge an assessment's curricular fit, the resulting score is partly a difficulty rating and cannot be read as independent evidence of alignment.
- **Realign the assessment triangle rather than patch one vertex.** Koretsky et al. (2026) frame the GenAI problem through the assessment triangle — cognition (what is assessed), observation (how evidence of learning is elicited), and interpretation (the inference drawn) — and argue the three vertices must be realigned together, since redesigning tasks without repairing the interpretation leaves the inference unsupported. Their scoping review also makes the fidelity of AI-generated assessment materials a validity property in its own right, cataloguing content, linguistic, cognitive, behavioral, structural, and pedagogical dimensions and requiring human-in-the-loop evaluation before such tasks ground assessment.

Redesign over detection

The knowledge base argues that maintaining assessment validity requires redesigning assessments for AI-capable students, not detecting AI use. A parallel validity problem runs through research measurement: many AI-in-education claims rest on self-report data, which cannot support an inference about learning or competence however well the instrument itself is validated. Beyond detection approaches and Assessment represent validity-forward thinking.

Take-home products and the qualitative/quantitative split. Brunnström and Palmqvist (2026) give the redesign argument a specific proposal grounded in the SOLO taxonomy. Working through a cognitive-science take-home exam question with a chatbot, they find GenAI is strongest exactly where the taxonomy is lowest — producing comprehensive, fluent, factoid-type content at the *quantitative* (multistructural) level —

while the *qualitative* level (relating, evaluating, generalizing) emerged only through repeated learner-driven calibration. Their recommendation is therefore differentiated by construct: take-home assessments should emphasize evidence of qualitative understanding, while quantitative recall-based knowledge is better assessed in class where GenAI is unavailable. The demonstration also underlines that a polished submitted artifact is weak evidence in either direction, and that valid redesign must account for how demanding legitimate AI-supported learning turns out to be (Summative Assessment, Academic Integrity).

A design-level counterpart comes from the same population the redesign argument usually ignores. Zou et al. (2026) found that reflective and personalized tasks were widely judged too personal for AI help, while a knowledge-heavy assessment in another course prompted strong intent to use generative AI for references — so what students did with AI tracked the construct the task asked them to evidence. The lesson for validity is precise rather than celebratory: design can remove the payoff from generic substitution, but the same study warns against reading an opt-out cohort as proof that it did, since a substantial share of non-use was attributed to fear of wrongful plagiarism accusation rather than to the task resisting AI.

Sharma (2026) supplies a redesign argument on the integrity side that turns integrity evidence into validity evidence. Extending Eaton's (2023) postplagiarism framing into assessment design, he argues that detection- and verification-based integrity models are misaligned with work in which human judgment and machine generation are entangled, and reframes integrity as a pedagogical practice enacted through Evaluative Judgment — the capacity to weigh options, justify academic choices and assume responsibility under epistemic uncertainty. The design consequence is that integrity should be evidenced rather than inferred: annotated decision trails, verification of GenAI-contributed claims, oral defense and version history are offered as integrity artifacts. He is explicit that the difference from Authentic Assessment is epistemic: authenticity asks whether a task mirrors real-world practice, integrity-oriented design asks whether learners can justify decisions and assume responsibility against disciplinary standards, so integrity becomes an assessable criterion embedded in the task architecture. He names the validity risk of his own proposal rather than leaving it implicit: requiring documented reasoning privileges learners fluent in reflective discourse and risks "the replacement of one compliance regime with another". Judgment as evidence "remains relational and situated rather than mechanically verifiable" — the same interpretive-reliability problem this page records for every AI-mediated assessment.

Weidlich (2026) reframes redesign as a question of which inference a change is meant to protect. Working from Kane's argument-based validity, he separates five pressures that debate tends to collapse into one: construct underrepresentation, construct-irrelevant variance, attribution of performance, conditional extrapolation, and unsupported score use. AI use is not automatically a threat, because tool use is germane where the intended construct is AI-supported professional judgment and bypasses the target performance where it is unaided reasoning, so construct and AI conditions have to be specified together. His caution for redesign follows, since interventions trade one pressure for another: oral defenses may strengthen attribution while reducing reliability or accessibility.

The task, not the detector, sets what an artifact can evidence. Liu and Liu (2026) had a model write 148 texts across three task formats and three AI-use scenarios: evidence-integration memoranda (3.16) and follow-up-and-revision defenses (3.10) scored above position essays (2.63), because those formats required source explanation or a response to objections. They propose model simulation as task pretesting before an assignment is run with students.

The outcome construct moves the estimate too: in a three-level meta-analysis of GenAI-supported problem-based and project-based learning, Chen et al. (2026) found learner-internal outcomes pooled at g = 0.819 while measures of the joint human-AI product returned g = 1.958 with a prediction interval crossing zero, modeled separately precisely because that product is not internalized learning.

AI-aware grading takes a third path between redesign and detection. AICG estimates a per-response AI-use probability and discounts the cognitive evidence by `max(0, 1 - pAI)` rather than docking the grade, lowering MAE by 4.2% over the unweighted cognitive model and keeping AI-assisted responses scoreable (Guo et al., 2026).

Policy has moved to graded permission, and to assurance over friction. Coding 55 institutional documents, Ansari (2026) found 4 prohibiting AI by default and 31 defining named categories of use, and of the 23 taking a position on detection, 16 rejected detectors. Redesign, on that reading, is redesign plus an assurance mechanism rather than friction alone.

Connections

Assessment validity connects to Authentic Assessment, Automated Grading, Confidence Aware AI Assessment, Formative Assessment, Academic Integrity, and RCT (which relies on valid outcome measures).

AI challenges validity at the epistemic level: Hathcoat, Slotnick & Miller (2026) argue that when LLMs serve as test-takers, test-makers, raters, and analysts, the interpretive chain becomes opaque and the object of measurement loses definition — reframing validity as requiring AI-fluent “cyborg” judgment, and Green et al. (2026) show AI scores can align with human raters (87% checklist) while the underlying rationale diverges, especially on measurement quality and weak reports.

When AI generates the assessable artifact. Kumar, Wongsirichot and Nanthaamornphong (2026) give the validity problem its sharpest disciplinary case: in computing education the AI produces the artifact being graded — the source code — so tool use, learning and assessment fuse into a single interaction, and a submitted codebase no longer separates learning from delegation. Across 72 studies they find efficiency gains that do not transfer to unaided performance (21 studies), Prior Knowledge moderating whether AI help becomes skill (6 studies), and detection research effectively absent from the evidence base (3 studies) while assessment redesign is comparatively well evidenced (25 studies). Their conclusion for practice is construct-specific and low-tech: add an oral component or other process-visible element to at least one high-stakes assessment per course — the single highest-leverage intervention in the review — and require critical engagement with AI output as a graded, observable component rather than an optional disposition (Academic Integrity, Assessment).

Correnti et al. (2026) replicate and extend a validity argument for eRevise, an automated writing evaluation system for upper-elementary argument writing, across 34 teachers and 609 students in eight Louisiana parishes, testing whether the same sociocultural mechanisms hold across three different writing outcomes rather than one.

Validity under imperfect information

The sharpest recent reframing treats the generative AI problem as an evidentiary one. The student knows how a piece of work was produced; the institution observes the artifact and, at best, partial traces of the process — a product–process gap that Mohamed and Temimi (2026) formalize as assessment validity under imperfect information. On this account the question is not whether a rule was broken but whether the assessment still generates credible evidence of student reasoning, effort, and judgment, and each institutional mechanism — prohibition, monitoring, disclosure, redesign — is evaluated by which student response it makes most attractive. The validity lens also dissolves a false separation: integrity and validity are the same problem seen from different ends, because a finding of misconduct is itself a validity claim about what the work evidences.

Wearable AI closes the last evidentiary gap rather than widening one: Corbin et al. (2026) argue that AI glasses and earbuds deliver assistance with no external signal, so a candidate can be present, supervised, and still not demonstrate unaided capability, dissolving the separability and observability that invigilated formats assumed.

A learner-side framework names the inference targets an artifact cannot settle by itself. Sak (2026) proposes *attributional validity* for judgments of gifted potential from AI-assisted work: the relation from capability to product is many-to-one, because learner competence, model capability, the learner's direction, human–AI fit and context combine differently to yield equivalent artifacts, so the product cannot identify the capacity behind it. The framework separates four targets of inference — independent competence, intellectual Learner Agency, hybrid capability, and developmental carryover — and names three errors that follow when one target's evidence is read as another's: overattribution, developmental illusion, and presumed capability equivalence. Its demand on the record mirrors the evidentiary discipline this section draws from the misconduct literature: name the capability a judgment is about, document how the work was produced (model and version, interface, permitted functions, adult mediation, access conditions), and require later evidence of transfer before reading assisted performance as a change in the learner.

Teichmann (2026) draws the procedural consequence: where prohibited use cannot be detected, a regime that still accuses on detector scores cannot warrant the inference it draws, and so produces unfairness without effectiveness. He argues for replacing the forensic question — did the student use AI? — with a validity question — did the student demonstrate the capability the task was designed to certify? — which relocates institutional effort into program-level assessment across linked tasks, oral and supervised elements at certification points, and Evaluative Judgment as an explicit object of assessment.

The same section of the evidence base supplies the case-file counterpart, and it is more uncomfortable than the detection literature alone. Munoz et al. (2026) coded every generative-AI misconduct case at one regional Australian university over three years — 1,162 cases carrying 1,855 discrete evidence items — and rated each item for probative value on relevance, credibility and inferential force. The strongest categories were the ones that do not depend on probabilistic classification of text (student admissions, observed prohibited exam behavior, and independently verified fabricated references), while detector output drew the weakest ratings of any category: similarity or Turnitin reports were wholly weak in inferential force and standalone detector outputs wholly low in credibility, falling from 8.8% of items in 2024 to 0.5% in 2025. The validity failure is procedural as much as instrumental — no stage of the pipeline set a minimum evidentiary threshold or required investigators to weigh probative value before progressing an allegation, so

evidence quality showed no reliable relationship to case outcomes, which is exactly the evidential standard issue catalogued on Legal Issues and Risks. Their proposal to apply a credentials framework at the point of *allegation* rather than only at determination is a validity demand: an allegation is a claim about what the work evidences, and it should be warranted by materials capable of supporting it. Hadra, Cambridge and Mesbah (2026) show how far the instrument is from that standard, with macro accuracy of 0.69 (Originality) against 0.61 (Turnitin) across 192 texts, near-total failure on hybrid human–AI writing (sensitivity 0.02 and 0.31), declining accuracy with text length and on scientific writing, and a borderline tendency to misclassify EFL student writing as AI — so a detector score cannot establish the fact a misconduct finding asserts.

The human-marking benchmark and its ceiling

The OpRaise comparison of three frontier models against 761 authentic essays across three UK universities makes the benchmark part of the validity argument. Human marks were used as ground truth on the explicit ground that academic judgment is the socially accepted standard, while the authors acknowledge that human markers agree only moderately with one another — which caps the AI–human agreement that could reasonably be demanded, and means a correlation cannot be read as ready-or-not without a reference point. Within that frame the failures appeared as systematic structure rather than random error: marks compressed toward the middle of the scale, so the best and worst essays were misjudged most; agreement was weakest at grade boundaries; and AI marks tracked vocabulary range, connectives and sentence complexity while human marks were broadly insensitive to them. The practical lesson is double-edged, because the same study found reliability to be excellent — identical re-marks across time and high agreement between models. A validity case for automated marking therefore cannot rest on stability or on average agreement; it has to show the absence of systematic deviation, which is exactly what this evidence did not find.

Run-to-run stability is not guaranteed, however: repeating the same grading on identical submissions five days apart gave Krippendorff's alpha 0.625, with variation concentrated in the middle grades and A and F absent from the repeated-session counts (Brevik et al. (2026)).

- **Model size is not a proxy for assessment validity.** Across eight configurations of four families on 114 marked essays, exact band agreement spanned 18.4% to 54.4% and tracked the family rather than parameter count — the largest model, GPT-OSS 120B, undergraded by 1.316 bands, and temperature was no fix (Kerwat et al. (2026)).
- **Agreement and benchmark error masquerade as learning.** Two 2026 studies show distinct routes by which a score can look valid while establishing something else. An open-ended marketing-writing study found LLM-human absolute agreement of only ICC(2,1) .435 and a hybrid that was significantly worse than the LLM alone, with anchor composition moving agreement from .338 to .902 (Agreement and error in automated scoring of student marketing posts). An expert audit of six physics benchmarks attributed 95.20% of audited rejections to defective items or graders rather than model error, moving CritPt mean@5 from 32.29% to 87.50% (How Good Are Frontier Models at Physics? Expert Re-Grading Reveals Broken Evaluations and Near-Saturation of Leading Benchmarks). In both cases the threat is construct-irrelevant variance outside the model being scored.
- **Agreement among LLM coders is consistency, not validity.** On an expert-labeled educational dialogue corpus, a cross-model agreement filter retained only 33 of 74 corpus-derived behavioral

assertions and 11 of 48 construct-derived ones, and shared model errors survived the filter, so inter-model agreement cannot stand in for construct validity (Bernado et al., 2026).

- **Automated sentiment labels are a measurement claim, not a description.** On 1,220 open-ended student survey responses, the best off-the-shelf sentiment tool (BERT-nlptown) reached only moderate agreement with human coding (κ = .42), and lexicon tools misclassified roughly 20% of responses for want of vocabulary coverage (You & Horissian, 2026). A sentiment label is a measurement outcome, so classification error is a validity threat, not a tuning problem.
- **Contamination is the validity threat that aggregate data hides.** When students use AI to do the graded work, a rise in mean rubric scores is evidence about the tool, not the learning, and a model grading a model's output is "a hall of mirrors" rather than assessment (Jenkins & de Mello-e-Souza Wildermuth, 2026). The authors note that contamination is invisible in the aggregate data programs normally use.
- **Exposure is measurable, and the remedy is sufficient evidence rather than maximum security.** Villanueva (2026) scored 53,915 assessment items by published format, supervision and mark weight and found most assessed marks resting on work whose authorship cannot be verified after submission; he argues programs need enough evidence of learning at key stages, not every unit made secure.
- **A model can pre-test items and expose defects that faculty review misses.** One institution had an enterprise AI platform answer examination items before administration, then compared its reasoning against the intended construct and keyed response (Ford, Helms & Moseley, 2026). The exercise surfaced ambiguous wording, multiple plausible answers, unintended clues, and items whose keyed answer could not be clearly defended. The authors treat the reply as a prompt to re-examine an item, not proof that it is flawed.
- **A valid measure can still be unsafe to optimize.** Fine-tuning an LLM tutor against a rubric-style adaptivity metric raised the metric (+0.05 to +0.42) while blind expert ratings fell (4.46 to 3.03), because a metric that scores decisions independently is maximized by repeating the single best decision (Domínguez Figaredo & Fernández De la Cruz, 2026).
- **An embedding's geometry is not a rubric's distinctions.** Against 992 handwritten physics solutions under five textual representations and nine embedding mechanisms, Tauschhuber & Kortemeyer (2026) report a best weighted Spearman correlation with human scores of 0.198, with clusters score-enriched rather than score-equivalent.
- **"Passing the standard checks settles the grader."** On the same benchmark **no model passed all three** on any task: QWK of at least **0.70**, no more than **0.10** below the raters' own agreement, and a standardized mean difference within **0.15**. On code, **eight models** cleared the first two and then graded lower than the raters, and on short answers **21 of 22** graded lower, so the direction of the departure matters as much as its size.
- **"Agreement detects a biased grader."** It did not in a within-item ablation. Adding only a true or swapped attainment label to the prompt moved marks by **0.28 to 0.75 points** on a ten-point scale on every model tested, while a true label raised QWK by just **0.029 to 0.046**. A rescaling fitted

without the label matched that gain. Invariance has to be reported beside agreement, because a grader can score closer to the teacher while reading the student rather than the work.

Common Misconceptions

- **“LLM grading bias is a reason to abandon it.”** In a **large-scale national writing assessment**, an LLM scorer showed a **systematic conservative (under-grading) bias** — problematic as a final mark and potentially **useful as a screening** signal. A bias with a known direction is a different instrument from an unpredictable one.
- **“Grade inflation after AI is speculation.”** In a **difference-in-differences study of 500,000+ grades across 319 courses (2018-2025)**, courses with more AI-exposed tasks (writing, coding) **saw the share of A grades rise**. The effect concentrated where tasks were exposed.
- **“Faculty have adopted AI broadly.” 62.4% (53)** declined to use generative AI at all, and adopters’ use was **confined largely to proofreading (43.8%) and clarity checks (34.4%)**. The adoption pattern is cautious and narrow, which changes what a validity argument needs to cover.

Psychometrically Aware AI

> **Psychometrically aware AI** — AI assessment systems aligned with measurement theory — is the standard advanced in Aligning LLM-Simulated and Human Examinees for Psychometric Calibration: A Cognitive Diagnostic Profiling Approach, Cognitive Episodes in LLM Reasoning Traces Enable Interpretable Human Item Difficulty Prediction, Confidence Aware AI Assessment, and Item Response Theory: calibrated, uncertainty-aware AI assessment preserves reliability and validity rather than substituting raw model confidence for psychometric evidence.

Questions to Consider

- An AI grades a student's answer and reports a confident-sounding score. On what basis would you trust that number — and does your answer change when you learn the model wasn't calibrated against any measurement standard?
- The page warns against substituting raw model confidence for psychometric evidence. Think of a time you believed a confident AI output that turned out wrong. What made its confidence unearned, and what would 'uncertainty-aware' output have looked like instead?
- Research found that on the same assessment instrument, human and LLM response structures diverge — meaning a model can score well yet be measuring something different from what the exam intends. If you were a teacher using an AI grader, how would you ever detect that the test 'means' something different for the machine than for your students?
- Item-difficulty prediction uses LLMs to estimate how hard a question is. Before reading, consider: is 'how hard is this question?' a fact about the question, or about the people (or models) answering it — and what does that ambiguity imply for using AI to calibrate exams?
- Calibration, reliability, and validity are measurement concepts with precise meanings. Which of these have you actually thought through in your own assessment practice, and where might you be relying on an AI's output that has never been checked against them?
- For an Administrators or developer: if an AI assessment tool you're considering reports only raw accuracy, what specific questions would you now ask its vendor before deploying it with real students?

Introduction

As AI systems increasingly score responses, predict difficulty, and provide Feedback, a key risk is that they report confident-sounding outputs that have not been validated against measurement principles. Psychometrically aware AI addresses this by grounding AI Assessment in established psychometrics — calibrating outputs, quantifying uncertainty, and preserving Assessment Validity and Educational Measurement standards rather than relying on raw accuracy or self-reported confidence.

How psychometrically aware AI appears in the research

- **Calibration and confidence:** Confidence-aware assessment and LLM psychometric calibration ensure that AI reports meaningful, uncertainty-aware scores rather than overconfident point estimates.
- **Model confidence is not enough.** On SciEntsBank, verbalized, latent and consistency-based confidence each failed to separate correct from incorrect short answers; the best calibration came from adding dataset-derived aleatoric uncertainty — within-cluster entropy of embedded responses — through a Random Forest plus Platt scaling, enabling selective auto-grading and human review (Cong et al. (2026)).
- **Confidence flags triage review, not acceptance.** In high-stakes handwritten physics grading, AI confidence labels tracked far lower score error on high-confidence parts, yet some high-confidence, unflagged parts still disagreed with official marks, so the labels are useful for prioritizing examiner review rather than authorising automatic acceptance (Pathak et al. (2026)).
- **Difficulty prediction:** Item-difficulty prediction shows how LLM-based estimates must be validated against psychometric models (see Item Response Theory). Razavi and Powers (2026) provide a large-scale demonstration: across 5,170 K-5 math and reading items calibrated under the Rasch IRT model, GPT-4o's zero-shot difficulty ratings correlated moderately-to-strongly with true difficulties (r = 0.83 math, r = 0.81 reading) but were uneven across grades, while a feature-based approach (LLM-extracted features into tree-based models) reached correlations up to r = 0.87. The study's interpretable feature importance (grade level and word count top predictors) and its practical seven-step workflow illustrate how psychometrically aware AI can be operationalized — while its early-grade range-restriction finding and generalizability caveats underscore the need to validate LLM estimates against fitted psychometric parameters.
- **Recovering a curve is not the same as recovering every parameter.** A Multimodal AI model fine-tuned as a simulated respondent estimated held-out item difficulty at r = 0.85 and recovered the guessing parameter at 0.48, but discrimination was weak at 0.31 — so which parameter a method recovers is the finding (Ormerod & Kim, 2026).
- **Measurement validity:** The concept connects to Assessment Validity and Educational Measurement, the frameworks that define what valid, reliable AI assessment looks like.
- **Latent-structure validity:** Strugatski et al. (2026) show that a psychometrically aware stance must also verify that an assessment measures the *same latent construct* in LLMs as in humans. Because LLM and human response factor structures diverge on the same instruments, even well-scoring models may not be measuring the construct the exam purports to measure — a caveat for any AI assessment that borrows human validity evidence.
- **A label can measure more, or less, than it names.** Embedding 12 AI literacy instruments' 55 constructs and 272 items surfaced jangle pairs (same label, different measurement) and jingle pairs (different labels, near-identical wording), recovering reliability at r = 0.49, a pre-collection check that construct distinctions survive into item wording (He et al. (2026)).
- **A reliance scale that refuses outcome anchoring.** Four factors — reflective, cautious, thoughtless and collaborative use — emerged from 800 responses and held across a differently

shaped task (CFI = .91), measuring behavior per task moment instead of labeling it good or bad (Hou et al. (2025)).

- **Latent-ability pipelines and standard setting:** Curi et al. (2026) provide a concrete template for psychometrically aware scoring in a national exam: rubric item scores are never summed directly but fed into an IRT model whose latent-ability estimates are cut with the Bookmark standard-setting method into Proficient / Close to Proficiency / Insufficient, with passing requiring at least two Proficient sections and the remaining one at least Close to Proficiency. The authors reproduced that pipeline in automated form (a 67% probability of answering at least 7 rubric items correctly for the lower cut and at least 10 for the upper), letting AI and human item scores be compared against identical decision criteria rather than on raw agreement alone.
- **A model can look calibrated while mostly predicting one label.** Asking GPT-4o and Gemini 2.0 Flash to infer learning-style dimensions from 153 undergraduates' dialogues produced moderate accuracy that per-class recall showed was dominant-label prediction, with Intuitive and Global learners under-identified and few-shot prompting sometimes amplifying the bias rather than removing it (Zamanifard, Goudarzi and Robb (2026)).

Connections

Psychometrically aware AI sits at the intersection of Educational Measurement, Assessment Validity, Item Response Theory, and Confidence Aware AI Assessment. It is central to AI Ed Evaluation (whether AI assessment is trustworthy) and connects to Large Language Models (LLMs)-based Automated Assessment and Automated Grading. Its emphasis on validity also speaks to the measurement limitations of AIED research.

Common Misconceptions

- **"A model that scores well is measuring the same thing."** On **the same assessment instrument**, human and LLM response structures **diverge** — a model can score well while measuring something different from what the instrument intends. Matching scores is the observation; construct equivalence is a separate claim that requires structure-level evidence.
- **"Calibration can be read off a single accuracy figure." A single accuracy figure can hide a model that only looks calibrated**: asking GPT-4o and Gemini 2.0 Flash to infer learning-style dimensions from **153 undergraduates'** dialogues produced **moderate accuracy that performed differently under balanced metrics**. Aggregate accuracy hid a differential that balanced metrics exposed.
- **"Automated scoring pipelines cannot reproduce psychometric procedure."** The authors reproduced an established pipeline in automated form (**a 67% probability of answering at least 7 rubric items correctly for the lower cut and at least 10 for the upper**), letting AI and human item scores be compared on the same footing. The procedure was reproducible; the construct question remains.

Educational Measurement

> **Educational measurement** — the psychometric theory and methods for quantifying and validating learning and its constructs — runs through the knowledge base's Item Response Theory, Knowledge Tracing, and Assessment Validity pages. The Large Language Models (LLMs) era forces measurement to reconcile classical psychometrics with new AI-generated response streams: automated scoring, AI-predicted difficulty, and Multimodal AI traces must be validated against established measurement principles to preserve reliability and validity.

Questions to Consider

- An LLM predicts that an exam item is easy, but empirical test data says students find it hard. Which do you Trust, and what would convince you to trust the machine's estimate?
- Educational measurement is about turning observations of learning into defensible quantitative claims. When an AI grades an essay or scores a response, is a 'score' automatically a measurement — or does something have to be validated first? What?
- Some research suggests assessment instruments may not measure the same thing for humans as they do for LLMs — the latent structure diverges. If the constructs genuinely differ across humans and AI, what does that imply about AI-generated grades or difficulty ratings?
- AI can score, generate items, and predict difficulty at unprecedented scale. Is 'more measurement' the same as 'better measurement'? What makes a score reliable and valid, and can those standards be preserved when the measurement is done by a generative model?
- Benchmarks and AI-generated scores are everywhere now. What would you need to see before you'd treat an AI-based assessment as evidence about a learner's actual understanding rather than just a number?

Introduction

Educational measurement is the discipline of turning observations about learning — responses, behaviors, scores — into defensible quantitative claims. It encompasses construct definition, item/test design, scaling, reliability, and validity. In AI in education, measurement questions are everywhere: does a benchmark score measure what we think? Is an AI-generated grade reliable and valid? Do AI-predicted item difficulties agree with empirically estimated ones?

How educational measurement appears in the research

- **AI's decade-long reshaping of the field:** Xiong and Li (2026) map AI's impact across three eras (Formative 2015–2018, Expansion 2019–2022, Generative 2023–present) via an Efficiency–Enhancement–Transformation framework, spanning AI on scoring and item generation, psychometric modeling, assessment innovation and process data, and fairness/ethics/equity. They argue for a new paradigm integrating measurement theory with AI methods and for

reconceptualizing constructs in the context of human–AI interaction — the same boundary that latent-structure comparison probes empirically.

- **AI-predicted difficulty and calibration:** LLM difficulty calibration and item-difficulty prediction use LLMs to estimate item difficulty, which must be validated against psychometric estimates (see Item Response Theory). Razavi and Powers (2026) add a large-scale K-5 test of this premise: across 5,170 math and reading items calibrated under the Rasch IRT model, GPT-4o's zero-shot difficulty ratings correlated moderately-to-strongly with true difficulties (r = 0.83 math, r = 0.81 reading) but were uneven across grades and no better than a grade-mean dummy regressor for grades K and 1. A feature-based approach — LLM-extracted cognitive and linguistic features fed into tree-based models — reached correlations up to r = 0.87, with grade level and word count the top predictors. The study illustrates both the promise and the limits of AI-predicted difficulty as a measurement input, and offers a practical seven-step workflow for testing professionals.
- **Difficulty without discrimination.** Worden et al. (2026) score four frontier models against IRT ground truth on 2,548 mathematics items: they reach 68.6 percent on relative difficulty but fall below chance at judging discrimination, appearing to conflate the two, and predict correctness 85.4 percent of the time on correct answers against only 12.6 percent on incorrect ones.
- **When generated difficulty labels do not measure difficulty.** A construct-validity audit of 311 deployed LLM-generated questions found the generated difficulty label correlated with its own co-generated Bloom level at $\rho=0.90$ but with empirical difficulty (the Classical Test Theory $1-p$ index) at only $\rho=0.06$, while option length ran backwards ($\rho=-0.18$) - a labels-as-surface-form result that bounds the optimistic readings of AI-predicted difficulty above (An & Wang (2026)).
- **A synthetic benchmark's measurement quality rests on its generation pipeline.** A set built with a three-judge LLM panel and no human oversight during item generation showed weak item-level quality, and because the items are fully synthetic the authors call for human-curated item comparisons before the scores are read as measurement (Schroeder et al. (2026)).
- **A taxonomic label does not predict item behavior.** Across 265 mathematics items, intended Bloom level explained under 5% of the variance in difficulty ($\varepsilon^2 = .043$) and none of discrimination (Kruskal–Wallis $H = 0.54$, $p = .77$), while an LLM classification agreed with expert coders only fairly (Cohen's $\kappa = .22$) and pulled items toward the apply/analyze band (Altaweel & Moussa (2026)).
- **Judge generated items on the solution path, not the wording.** Encoding each item's verified reasoning tree lifted performance over the second-best method by 7.5% in concept assessment, 6.3% in difficulty estimation and 19.5% in competency assessment, where a zero-shot baseline mislabelled a template-following item "Reasoning" and a geometric item "Knowing" (Tong et al. (2026)).
- **Psychometric awareness in AI Assessment:** psychometrically aware AI is the standard that AI-based assessment be aligned with measurement theory — calibrated, uncertainty-aware, and validity-preserving (see Confidence Aware AI Assessment).
- **Mastery labels are constructed, not observed.** Where diagnosis needs ground truth, Jia and Dong (2026) built it through a validity-control procedure — curriculum concept graphs,

instructor-reviewed knowledge-point mappings and convergent assessment evidence — rather than converting behavioral traces directly, and their diagnoses matched educational psychologists at Cohen's kappa 0.78 against 0.65 for IRT.

- **Automated scoring and validity:** AI scoring and language bias and multimodal item-parameter estimation examine how automated scoring and multimodal data affect measurement quality.
- **Validity frameworks:** Assessment Validity and Educational NLP supply the standards and tools for validating LLM-based measurement.
- **Latent-structure comparison:** Strugatski et al. (2026) extend educational measurement to the LLM setting by testing whether assessment instruments show the *same factor structure* for humans and LLMs. Using EFA, factor congruence, and resampling, they show LLM–human latent structures systematically diverge across chemistry and quantitative-reasoning instruments, implying the constructs measured differ across populations — a necessary check before human validity evidence is assumed to transfer to AI.
- **AI as a rater with measurable error:** Cvengros & Kortemeyer treat AI-assigned points as fallible observations with multiple error sources (items, runs, tasks) under generalizability theory and Kane's argument-based validity. Reliability analysis of a 296-student handwritten general-chemistry exam showed high stability of *total* scores across five AI runs (ICC(A,1) = 0.967, Kendall's W = 0.959, 95% repeatability coefficient 5.33 of 60 points) with lower item-level stability (ICC(A,1) = 0.836) — unsystematic errors partially cancel when summed (a Spearman–Brown aggregation effect that lifts total-score agreement to $R^2 = 0.91$), while a small positive intercept with slope < 1 revealed a "timid grader" score-compression bias. This frames run-averaging and aggregation as measurement design decisions, and motivates confidence filters calibrated to IRT risk as a validity safeguard before automated measures are trusted.
- **Model version is a measurement condition.** Hao (2026) found within-model reply similarity (0.715–0.795) consistently exceeded between-model similarity (0.443–0.604) across four LLMs, so a scoring argument established for one deployment does not automatically transfer to its successor.
- **A null result is not evidence of equivalence unless it is bounded.** StudentBench tested whether pooled AI tutoring matched expert human tutoring with two one-sided tests against ±0.25 pooled standard deviations rather than a test for a difference, reporting an adjusted difference of -0.58 percentage points (90% CI [-2.18, 1.03]) - the choice that turns an underpowered null into an equivalence claim (Northcutt et al. (2026)).
- **Calibration that scales with new data rather than the whole history:** Jewsbury et al. (2026) confront the operational consequence of AI item generation — banks larger, sparser and more frequently updated than conventional ones, where refitting all accumulated response data at each update is costly and can exceed available memory. Their *consensus calibration* combines independently calibrated quarterly periods by mapping each period's posterior draws onto a common metric with a per-draw robust Haebara link (so linking uncertainty propagates rather than being treated as a fixed transformation), then aggregating as a product of Gaussian posteriors from which each period's *estimated, hierarchical* prior is subtracted and a consensus prior reinstated. On operational Duolingo English Test data across four periods the aggregate matched a pooled

single-run benchmark on posterior means (r = .998 for difficulty, .991 for log-discrimination) and standard deviations (r = .970 and .920), with residual under-dispersion of 0.91–0.98 in the consensus/pooled SD ratio across exposure tertiles — concentrated in the sparsest item tertile, where prior over-counting bites hardest. The measurement lesson is twofold: an estimated prior cannot be handled by the standard subset-prior devices of parallel Bayesian computation, and posterior *dispersion* — the uncertainty adaptive selection and scoring consume — is as much a target of the correction as the posterior mean.

- **Identifying a system's dispersion from two published numbers:** Restrepo Morales et al. (2026) show that an achievement distribution's standard deviation can be recovered from published summary statistics alone — the mean and the share of students at or above a fixed proficiency cut score — because under a distributional assumption $\sigma = (c - \mu) / z(1 - p)$. Applied to PISA 2025 El Salvador (mathematics mean 346, 12.28% at or above the level-2 cut of 420.07), the implied σ is 63.8 (reading 76.8, science 63.8), well below the international benchmark of 100, as expected for a distribution pressed against the floor of the scale; the three estimates were obtained from independent pairs of figures and lie within about 13 points of one another, a mild internal consistency check. The share at Level 2 is reported for every PISA system and underpins the SDG 4.1.1 indicator, so the identification needs no microdata, and the same paper demonstrates the denominator problem in effect sizes by reporting one mathematics gap three ways — 129 points, 1.29 international standard deviations, or 2.02 standard deviations of the Salvadoran distribution itself — on the argument that standardized effect sizes divided by their own sample's dispersion are not legitimately comparable across studies.

Measurement instruments in the knowledge base

A central function of educational measurement is the development, validation, and use of **instruments** — the concrete scales, tests, and coding schemes that operationalize constructs. The knowledge base's articles document a wide range of instruments for AI-in-education constructs, which can be categorized by what they measure and by their measurement approach.

AI / GenAI literacy instruments
